Diltiazem	USP Cardizem	5-mg/ml vial; USP powder	Supraventricular tachycardia	0.5 mg/kg IV every 30 minutes up to 1.25 mg/kg total dose
Propranolol	USP Inderal	1-mg vials	Unresponsive tachyarrythmias	0.03 mg/kg IV

Propafenone	Rhythmol	150- and 300-mg tablets	Sustained ventricular tachycardia; atrial fibrillation	2 mg/kg per os q8h
Bretylium tosylate	Bretylium	500-mg/10-ml vials	Life-threatening or refractory ventricular arrhythmias	3–5 mg/kg IV
Furosemide	Lasix Furosemide USP	5% solution, 50 mg/ml	Edema	1–2 mg/kg as needed
Dobutamine	Dobutrex	20-mg vials for infusion	Cardiogenic shock, hypotension, complete atrioventricular block (emergency therapy)	1–5 μg/kg/min
Hydralazine	Apresoline Hydralazine USP	50-mg tablets	Mitral regurgitation	0.5–1.5 mg/kg q12h
Quinidine sulfate (oral); quinidine gluconate (IV)	USP Cardioquin Quinaglute	50-g jars of quinidine sulfate powder, USP; tablets; quinidine gluconate for injection, 80 mg/ml	Atrial arrhythmias, ventricular arrhythmias	22 mg/kg per os 1–10 mg/kg IV, total dose (see Box 8-11 for details)
Magnesium SO_4	USP (filter)	Dissolve 20–25 g in sterile water; filter	Ventricular tachycardia	IV infusion at 1 g/min to effect, up to a maximum of 25 g
Dexamethasone	Azium Azium SP	Injection, 4 mg/ml	Ventricular tachycardia, complete atrioventricular block	0.1 mg/kg to 0.22 mg/kg IV or IM
Glycopyrrolate or atropine	Robinol Atropine USP	0.2 mg/L 0.4 mg/L	Sinus bradycardia, vagal-induced arrthythmias	0.005 to 0.01 mg/kg IV
Sodium bicarbonate	Bicarbonate sodium, USP	Approximately 1 mEq/ml, available in ampules or bottles	Hyperkalemia, atrial standstill; quinidine toxicosis	1 mEq/kg IV; can be repeated
Phenylephrine HCl	Neo-Synephrine	10 mg/ml	Arterial hypotension, excessive vasodilation, quinidine toxicosis	0.01 mg/kg to effect

* CHF, Congestive heart failure; IV, intravenous(ly); IM, intramuscularly.

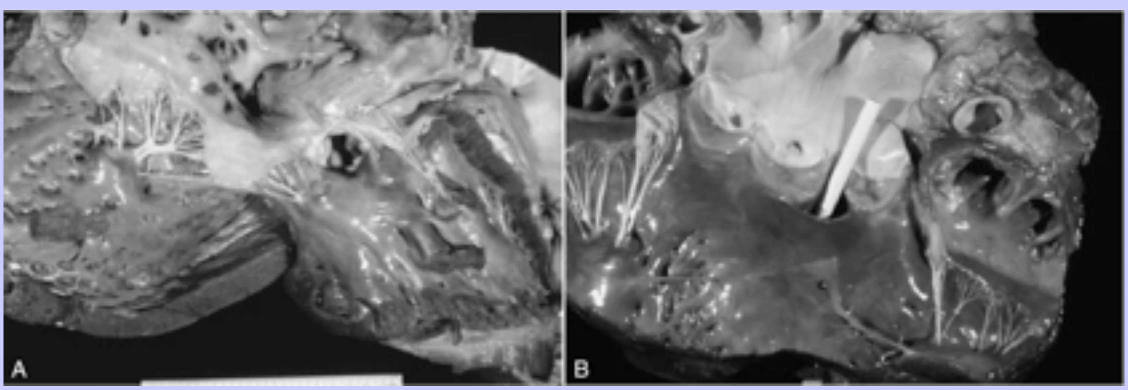
Although some defects are lethal to the neonate, others are compatible with life but limit peak performance or reproductive value. Most cardiac malformations involve shunting of blood, with the VSD most often recognized (Figures 8-26 to 8-28). Isolated malformations leading to valvular stenosis or incompetency are uncommon. Rare lesions such as subaortic stenosis,[530] double-outlet right ventricle, transposition of the great vessels,[147,155] bicuspid

pulmonary valve, pulmonary stenosis,[158] persistent fetal circulation,[549] hypoplastic left heart syndrome,[148,149] mitral valve malformation,[439] endocardial fibroelastosis,[60,550] total anomalous pulmonary venous return, and aortic origin of the pulmonary artery are not discussed further. Some of the more frequently recognized defects[297] are described later.

8.6.1 PATHOGENESIS

The underlying genetic factors guiding normal development of the heart and those leading to cardiac malformation are understood incompletely. Cardiac morphogenesis is complicated, but understanding elementary aspects of cardiac development is helpful, especially as these pertain to congenital heart disease.[551] Among these fundamentals are the septation of the atria, the anatomic components forming the ventricular septum, the separation of the great vessels, and the normal fetal circulation.

Figure 8-26 Pathologic evaluation of ventricular septal defects. **A,** Opened right ventricle from a mare demonstrating a perimembranous septal defect opening just beneath the septal leaflet of the tricuspid valve. Aortic valve cusps are visible through the defect. Congestive heart failure occurred late in life, after the development of atrial fibrillation. **B,** A large ventricular septal defect in a horse. A probe runs through the defect. The dorsal location immediately beneath the right and the noncoronary cusps of the aortic valve are notable. Ostia of both coronary arteries are also evident.

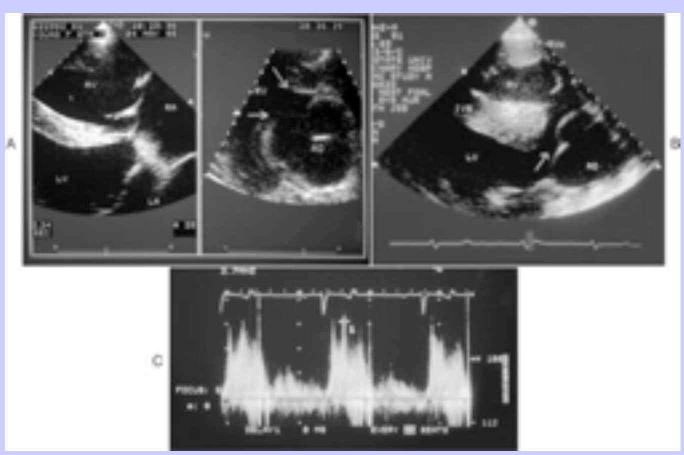


The right and left atria are separated by incorporation of the right horn of the sinus venosus and through development and fusion of two prominent membranes, septum primum and septum secundum. The endocardial cushions close the gap between the atrial and ventricular septa. These tissues also contribute to the atrioventricular septum, that segment filling the gap between the mitral valve septal insertion on the left and the more ventral tricuspid valve insertion on the right. The foramen ovale, a normal atrial structure, is located approximately in the middle of the atrial septum and creates a passageway for blood to flow from right to left

atrium in the normal fetus. The equine foramen ovale resembles a fenestrated finger cot and is visible with echocardiography as a mobile septal membrane even in healthy, full-term foals. This interatrial path may persist in foals with pulmonary hypertension and elevated RA pressures. Failure of normal development in any of these tissues can lead to an atrial septal defect (ASD), which is typically designated by the location of the defective membrane (Figure 8-29).

The ventricular septum is a complicated partition that includes a small membranous portion located opposite the aortic root and craniodorsal to the tricuspid valve, an inlet septum below the septal tricuspid leaflet, an apically 399
located muscular or trabecular septum, and a dorsal outflow segment that separates the subaortic and the 400
subpulmonic infundibulum (see Figure 8-28). The ventral atrial septum connects to the dorsal ventricular septum by growth and differentiation of endocardial cushions. These swellings also form the atrioventricular valves. Insufficient development of any embryonic component of the ventricular septum can lead to a VSD, the most common cardiac malformation in horses. Defective differentiation of the endocardial cushions causes various combinations of an ostium primum (ventral) ASD, an inlet VSD, malformation of the atrioventricular valves, or common atrium with a single atrioventricular valve.

Figure 8-27 Echocardiograms demonstrating ventricular septal defects (see also Figures 8-22, *A;* 8-23, *A;* and 8-31). **A,** This subaortic ventricular septal defect is not evident from the long-axis image *(left panel)* but is visible in the short-axis tomogram *(arrows)*. This Quarter Horse gelding also had pulmonic stenosis. The elevated right ventricular pressures have led to significant right ventricular enlargement with bulging of the septum toward the left ventricle. **B,** Malalignment and a perimembranous septal defect associated with prolapse of an aortic valve leaflet across the defect *(arrow)*. (*RVW,* Right ventricular wall.) **C,** A continuous wave Doppler study recorded from a filly with a large, unrestrictive ventricular septal defect. The maximal velocity of 3.1 m/sec predicts a pressure difference of less than 40 mm Hg.



The aorta and pulmonary artery begin as a single vessel in the conus arteriosus. This common vessel, the truncus arteriosus eventually is partitioned by migration of the conus and development of the conotruncal and spiral septa. Twisting of the spiral septum produces appropriate alignment (concordance) of the great vessels with their respective ventricular chambers. The descending aorta and pulmonary artery are connected by the ductus arteriosus, which carries fetal blood from pulmonary artery to descending aorta. Maldevelopment of conotruncal or spiral septal tissues leads to complicated congenital heart defects in the horse, including persistent truncus arteriosus[552] and double-outlet right ventricle.[520] Persistent patency of the ductus arteriosus is rare (Figure 8-30).

An understanding of the fundamental circulatory patterns of the fetus is helpful. Two circulations exist, one serving the embryo and the other communicating with the placenta. Functionally, two right-to-left shunts exist: one across the foramen ovale and the other across the ductus arteriosus. The fetal lungs are collapsed, pulmonary 400
vascular resistance is high, and pulmonary blood flow is minimal. Desaturated blood returning from the fetal 401
tissues is collected in the cardinal venous system and enters the sinus venosus and right atrium. This blood is largely earmarked for the right ventricle and pulmonary artery. Most pulmonary arterial flow is diverted through the ductus arteriosus to the descending aorta and placenta to be oxygenated. Well-saturated blood returning across the umbilical veins is delivered by the caudal vena cava to the right atrium where it preferentially crosses the foramen ovale to enter the left atrium, left ventricle, and ascending aorta. These patterns change dramatically with foaling. As the lungs expand, pulmonary vascular resistance falls, and pulmonary blood flow increases. The resultant increase in LA pressure functionally closes the foramen ovale within the first 24 to 48 hours of life. Similarly, inhibition of local prostaglandins leads to functional closure of the ductus arteriosus within 72 hours in 401
most full-term foals. Persistence of the right-to-left shunts, especially at the level of the foramen ovale, can occur 402
in premature foals or those suffering from severe pulmonary disease with associated pulmonary hypertension. In these cases, shunting across the foramen ovale represents an additional mechanism for arterial desaturation and tissue hypoxia.

Figure 8-28 Pathophysiology of ventricular septal defects *(VSD)*. See text for details. *LA,* Left atrium; *RA,* right atrium; *LVDP,* left ventricular diastolic pressure; *RV,* right ventricle, *RVH,* right ventricular hypertrophy. 8.6.2 CLINICAL PATHOPHYSIOLOGY OF SHUNTS

Fundamental to understanding cardiac malformations in the horse is an appreciation of shunt physiology and the potential responses of the heart and circulation to a shunt.[518] Shunting can be defined as abnormal deviation of blood flow between the systemic (left) and pulmonary (right) sides of the circulation. Possibilities include left-to-right, right-to-left, and bidirectional shunting.

Systemic-to-pulmonary (left-to-right) shunting is the expected result of an ASD, VSD, or patent ductus arteriosus (PDA) so long as systemic pressures and resistance exceed that on the right side. Even in cases of abnormal ventricular-arterial development, as with persistent truncus arteriosus, double-outlet right ventricle, or univentricular heart, the clinical findings of a left-to-right shunt may predominate unless obstruction to blood flow occurs at the pulmonary valvular or arteriolar levels. The actual shunt volume carried to the lungs depends on the caliber (or restrictive nature) of the lesion orifice and the relative resistances between the systemic and pulmonary circulations. Shunting may not be significant after foaling because pulmonary vascular resistance is still high and systemic arterial and LV pressures are low for a number of weeks after birth. Eventually left-to-right shunts increase pulmonary arterial flow and augment pulmonary venous return. The horse easily handles small shunts through mild left-sided dilation and hypertrophy. When the pulmonary to systemic flow ratio exceeds about 1.8:1, the shunt is usually considered clinically significant. The result is more noticeable volume overload of the left atrium and left ventricle. The greater the shunt, the higher the potential for left-sided or biventricular CHF from chronic ventricular systolic or diastolic dysfunction. Pulmonary hypertension can occur in the setting of left-to-right shunting from combinations of increased flow, inadequate development of pulmonary arterioles, and LV dysfunction. Thus consequences of significant left-to-right shunting may include any of the following: exercise intolerance, tachypnea, pulmonary edema, respiratory distress, pulmonary hypertension, atrial fibrillation, pleural effusion, jugular venous distention, or ventral edema. The foal may be smaller than expected and may have a history of antibiotic therapy for presumed bouts of pneumonia.

Right-to-left shunting stems from a different pathophysiologic state and produces another clinical presentation. When a shunt is complicated by a right-sided obstruction adjacent to or downstream from the defect, right-to-left shunting develops as right-sided pressures exceed those on the left side. This can occur in the neonate, as in tricuspid valve atresia with ASD or pulmonary valve atresia with VSD. Conversely, elevated right-sided resistance can develop more chronically from pulmonary vascular disease. For example, a large left-to-right shunt can induce medial hypertrophy and intimal thickening of pulmonary arterioles elevating pulmonary vascular resistance and decreasing the left-to-right shunt. Though uncommon, the resultant pulmonary hypertension may become severe (Eisenmenger's physiology) and reverse the shunt to right-to-left. In these cases the left-side heart chambers are small and the right ventricle is hypertrophied to achieve systemic blood pressure.

The entrance of desaturated blood from the right to left side of the circulation causes hypoxemia. Thus the consequences of a significant right-to-left shunt may include low arterial Po_2, tissue hypoxia, cyanosis, exercise intolerance, mild to moderate polycythemia, hyperviscosity of blood, and stunting of growth. Congestive heart failure is rare, but sudden death can occur, presumably from arrhythmia. The degrees of hypoxemia and cyanosis in a right-to-left shunt depend on overall pulmonary blood flow; this is a pivotal concept. If pulmonary flow is diminished, as with tetralogy of Fallot, tricuspid atresia, and pulmonary atresia with restrictive pulmonary flow, the contribution of the left ventricle to aortic flow (and thus oxygenation) is low. In some instances, right-to-left shunting develops in the setting of increased pulmonary blood flow, as with truncus arteriosus or double outlet

ventricle. These lesions cause less hypoxemia because the amount of oxygenated blood reaching the left ventricle is normal to increased. In such situations cyanosis from right-to-left shunting may be negligible and the clinical condition of left-sided or biventricular CHF may predominate. If the increased pulmonary flow is sufficient to minimize the arterial hypoxemia but not cause CHF, survival beyond 5 years of age is possible.

8.6.3 VENTRICULAR SEPTAL DEFECTS

VSD is the most important congenital heart disease of horses.[*] A genetic basis is likely in the Arabian breed. In the authors' experience, VSD also occurs regularly in Standardbred horses and in Quarter Horses. The VSD often accompanies more complicated malformations.

The location of a VSD depends on the embryogenesis of the lesion and influences the designation and even the clinical manifestations of the defect. The nomenclature of VSDs is confusing, but one may recall it best by 402
considering the main components of the normal ventricular septum (see Figures 8-26 to 8-28). In most cases a 403
VSD is located dorsally (high) on the ventricular septum, below the right or noncoronary cusp of the aortic valve on the left side, and craniodorsal to the septal tricuspid leaflet on the right.[428] Such defects generally are termed *perimembranous* or perhaps more correctly *paramembranous*. Most of these holes are also subcristal because the VSD is located caudoventral to the supraventricular crest that muscle separates the right ventricular inlet and outlet. However, a large paramembranous defect may extend under the tricuspid valve toward the inlet septum or advance across the supraventricular crest toward the outlet septum. The (conotruncal) septal defects associated with tetralogy of Fallot (Figure 8-31) and with pulmonary atresia are usually large and fall into the latter appellation. Sometimes the aortic root is displaced ventrocranially and straddles the defect, creating a malalignment VSD that is characteristic of the tetralogy of Fallot but also can occur with large paramembranous defects. Malalignment is clinically significant because the right or noncoronary cusp of the aortic valve is likely to prolapse into the defect, leading to aortic regurgitation (see Figure 8-27, *B*). A less common location for a VSD is immediately ventral to the septal tricuspid valve within the muscular septum. Such inlet VSDs are typical of an endocardial cushion defect and may be related to a primum ASD or even a persistent common atrioventricular canal, which creates a gap between all four cardiac chambers. A subaortic VSD that communicates with the outlet portion of the ventricular septum directly below the pulmonary valve is variably termed an *outlet, supracristal, subpulmonic, subarterial,* or *doubly committed* VSD. This lesion also places the aortic valve at risk for prolapse. Finally, apical muscular (trabecular) defects or multiple VSDs are rare but have been observed in horses. Some of these are small, whereas others have been enormous.

Figure 8-31 A two-dimensional echocardiogram from a filly with tetralogy of Fallot. A large ventricular septal defect is present between the right ventricular outflow tract *(RVOT)* and the subaortic region (*Ao,* aortic valve cusp observed in the oblique plane). The pulmonary artery eventually widens into a poststenotic dilation *(PSD)*. Shunting is bidirectional in this case.

Many VSDs close spontaneously in human beings, but whether this is common in horses is unknown. However, imposition of a cardiac valve can diminish the flow across a VSD. For example, scar tissue that ensnares the septal tricuspid leaflet may occlude the rim, or even a major portion of a VSD, by rendering the defect functionally smaller and possibly creating a hyperechoic aneurysm on the right septal surface. Large defects associated with malalignment of the ascending aorta to the upper border of the remaining septum often are associated with prolapse of an aortic valve leaflet (or of the aortic root) into the defect. Aortic prolapse effectively can close even a large VSD, but at the risk of permitting chronic aortic valve insufficiency over time. 428

The pathophysiology of the uncomplicated VSD is that of a left-to-right shunt as described previously (see Figure 8-28). Much of the shunt volume pumped by the left ventricle is ejected immediately into the pulmonary artery. As pulmonary flow increases, venous return to the left atrium and left ventricle increases, causing LV dilation and hypertrophy recognizable by echocardiography. Thus the left (not the right) ventricle performs most of the extra volume work. Shunting is more severe if the aortic valve prolapses with aortic regurgitation or if MR develops because of LV enlargement. If the shunt is large and pulmonary arteriolar resistance does not increase significantly, LV failure can develop. Failure is most likely to occur early in life, as the high fetal pulmonary vascular resistance declines, but late cases of CHF (with atrial fibrillation) also occur. The degree of RV hypertrophy and enlargement varies, depending on the location and size of the septal defect and pulmonary vascular resistance. Large nonrestrictive defects cause the two ventricles to behave as a common chamber, allowing ventricular pressures to equilibrate and leading to severe RV hypertrophy and pulmonary hypertension.

The clinical features of VSD vary.[428,518] Clinical signs may be absent, and one may identify the defect as an incidental finding. A mature horse may be presented for poor performance or with atrial fibrillation. Foals may be symptomatic for pulmonary edema or biventricular heart failure. Most commonly, a murmur is detectable

incidentally during the physical examination for another problem or during a prepurchase examination. Because most defects communicate near the RV inlet septum, the most consistent physical examination finding is a harsh, holo- or pansystolic murmur that is loudest just below the tricuspid valve and above the right sternal border. An ejection murmur (one to two grades softer) of relative pulmonic stenosis (from increased flow) is usually evident over the left base. The S_2 may be split more widely than normal because of disparate ventricular ejection times; the pulmonic component of S_2 may be more tympanic if pulmonary hypertension is present. In contrast, the murmur of a subarterial (subpulmonic or supracristal) VSD is loudest over the left cranial base as the high-velocity flow enters just below the pulmonary artery. When VSD is associated with complex cardiac malformation, the murmur is likely to be loud over each side of the thorax. One cannot judge the severity of the defect based on murmur intensity. In some cases a small defect may be loud; whereas a large, less restrictive defect may cause a murmur related entirely to pulmonic stenosis. If significant LV volume overload occurs, the mitral valve may become incompetent and a holosystolic murmur of MR may be evident over the left apex. The rare trabecular (muscular) VSD also may create a systolic murmur over the left or right apex. If significant cardiomegaly develops, atrial and ventricular premature complexes, or even atrial fibrillation, may occur. A holodiastolic murmur of aortic regurgitation indicates prolapse of an aortic cusp and the likelihood that the lesion is large. Substantial aortic regurgitation is associated with a hyperdynamic arterial pulse. The VSD associated with pulmonary atresia or persistent truncus arteriosus may not create a substantial murmur, but the increased flow through the dilated single vessel usually creates a loud ejection murmur over each side of the chest.

Diagnostic studies confirm the lesion and importantly assess the hemodynamic burden. Noninvasive studies are sufficient for diagnosis in almost every case, and cardiac catheterization has become unnecessary except in rare instances. The performance history is a useful overall indicator of effect, and the horse with an excellent work history is unlikely to have a large defect. The ECG is unreliable for diagnosing cardiomegaly in horses but is indicated in the setting of an arrhythmia. Thoracic radiography can be useful in foals to demonstrate cardiomegaly (see Figure 8-19, *A*), the pulmonary circulation, and the lungs and pleural space. Two-dimensional echocardiography and color Doppler imaging establish the diagnosis.[400] M-mode studies and spectral Doppler examinations are useful for assessing the hemodynamic burden of the defect.

Two-dimensional echocardiography successfully delineates the VSD in virtually all cases, provided one obtains a sufficient number of imaging planes (see Figures 8-22, 8-23, and 8-27). Collecting long-axis images of the LV outflow tract and aortic valve is important, as well as collecting short-axis images at the level of the LV outflow tract, just below the aortic leaflets. The typical paramembranous defect appears under the aortic valve and adjacent to the septal leaflet of the tricuspid valve. A true defect is characterized by an echogenic tissue interface; whereas an area of false echo dropout tends to be gradual. One can image most defects in orthogonal (long-axis/short-axis) planes. The right coronary artery of the horse is large and may be confused with a subarterial (supracristal) VSD. One also should note that an inlet VSD (ventral to the septal tricuspid valve) might not be easily visible in standard planes. Tipped or oblique views that show both atrioventricular valves may be required. Similarly, finding a muscular, apical, or small subarterial defect requires more imaging experience and is greatly assisted by color Doppler studies.

One should attempt to identify the largest diameter of the defect in complementary planes, and compare this with the size of the aorta, because orifice size is an important prognostic factor. Although two-dimensional sizing of the VSD has limitations, a defect exceeding 2.5 cm in diameter or a VSD/aortic root diameter of greater than 0.4 cm identifies a large defect with greater likelihood of clinical signs. Furthermore, two-dimensional or M-mode evidence of left-sided cardiac dilation, right ventricular enlargement, or significant dilation of the main pulmonary artery suggest a hemodynamically significant VSD and one more likely to affect performance or survival.

Color Doppler studies are best for identifying shunting across a VSD. Typically, high-velocity, turbulent flow enters the right ventricle during systole with low-velocity, uniform color shunting noted during diastole. Color Doppler imaging is helpful for identifying a VSD with atypical location and also may identify aortic regurgitation in some horses. Continuous wave Doppler is used to estimate the pressure difference between the two ventricles, for velocity (in meters/second) is proportional to the instantaneous pressure difference across the ventricles ($\Delta P = 4V^2$). A small VSD is restrictive to flow, and the peak shunt velocity generally exceeds 4.5 m/sec, assuming proper alignment to shunt flow. Should pulmonary hypertension develop related to increased pulmonary flow, left-sided heart failure, or pulmonary vascular injury, the velocity of left-to-right shunting will be lower, and one may identify a high-velocity jet of TR (>3.5 m/sec).

Potential outcomes of the isolated VSD include tolerance of the lesion; partial or complete closure of a VSD by adherence of the septal tricuspid leaflet, fibrous tissue, right ventricular hypertrophy, or aortic valve prolapse; progressive aortic regurgitation; atrial fibrillation; left-sided or biventricular CHF; pulmonary hypertension (with left-to-right shunting); or reversal of the shunt with development of arterial hypoxemia and cyanosis. The latter 404
would be caused by severe pulmonary vascular disease (Eisenmenger's physiology) or fibromuscular obstruction 405
in the right ventricular outlet leading to subpulmonic stenosis. The horse with a small-diameter paramembranous defect, high-velocity left-to-right shunt, mild cardiomegaly, normal right ventricular cavity, and normal heart rhythm probably has a restrictive VSD that will be well tolerated. Most of these animals can perform sufficiently in the show ring, as a hunter-jumper, or even as an endurance or racehorse. Large defects that are associated with echocardiographic evidence of moderate to severe cardiomegaly, right ventricular hypertrophy, aortic root prolapse, or Doppler evidence of pulmonary hypertension are prone to complications and carry a less favorable prognosis for performance or life regardless of current clinical signs.

Definitive therapy for VSD involves cardiopulmonary bypass surgery and is impractical. Surgical banding of the pulmonary artery elevates right ventricular pressures and reduces left-to-right shunting; however, this procedure also limits CO and is not advisable. Should CHF or atrial fibrillation develop, one can consider medical therapy in selected cases, but even if the response to treatment is good, the owner should not use the horse. Treatment involves daily administration of digoxin and furosemide (with or without an ACE inhibitor if economics are not an issue) as discussed previously. In the authors' view, one generally should discourage breeding of affected animals, especially in Arabian horses.

8.6.4 ATRIAL SEPTAL DEFECTS

ASDs, including endocardial cushion defects, are uncommon in foals.[*] As indicated previously, an ASD may involve different portions of the atrial septum. Abnormal atrial septal patency is more likely to be observed with complex congenital cardiac defects, particularly with tricuspid or pulmonary atresia. An isolated ASD may be clinically insignificant, with no significant murmur or clinical signs. Moderate to good exercise capacity may be expected because left-to-right shunting decreases as the systemic to pulmonary vascular resistance ratio declines with exercise. In the case of a large ASD, left-to-right shunting leads to right-sided volume overload and pulmonary overcirculation. Such defects are visible with echocardiography (see Figure 8-29), and Doppler echocardiography can confirm the direction of the shunt and estimate its severity. Atrial fibrillation may occur along with ASD.

Complete endocardial cushion defects rarely occur, but are serious, usually leading to CHF or atrial fibrillation at an early age. This developmental defect typically consists of a large ASD of the primum and atrioventricular

septum, a common atrioventricular valve leaflet, and a defect in the inlet portion of the ventricular septum. The ventricles may be partitioned normally, unequally with one rudimentary ventricular chamber, or not at all, creating a single ventricle. In the most severe cases a common atrioventricular canal, single large atrioventricular valve, and common single ventricle exist from which both great vessels exit. The clinical signs of a complete endocardial cushion defect vary. The foal with an unobstructed outlet to the pulmonary arteries is hemodynamically similar to one with a large VSD. When a common ventricle is present, one may observe varying degrees of cyanosis. A systolic murmur is typical and may reflect flow across the VSD, left-to-right shunting (relative pulmonary stenosis), or atrioventricular valve regurgitation. An echocardiographic evaluation reveals an ASD involving the primum portion of the atrial septum; a VSD involving the muscular, inlet segment of the interventricular septum; and malformed atrioventricular valves. Doppler echocardiography reveals the intracardiac shunts and atrioventricular valvular regurgitation. CHF may supervene. The prognosis is poor.

* References 121, 149, 151, 153, 456, 505, 537.

8.6.5 PATENT DUCTUS ARTERIOSUS

PDA is a rare congenital cardiac defect in foals and is detected most frequently in combination with other, more complex congenital cardiac defects (see Figure 8-30).[*] The ductus arteriosus is a fetal vessel, derived from the left sixth aortic arch, that permits shunting from the pulmonary artery to the descending aorta in the fetus. At birth the ductus arteriosus normally constricts, in response to increased local oxygen tension and inhibition of prostaglandins. The ductus arteriosus is functionally closed 72 hours after birth in the majority of foals. If the ductus arteriosus does not close, a left-to-right shunt from the aorta to pulmonary artery occurs. Although some hereditary predisposition to the development of this congenital lesion in other species may occur, this lesion is so rare as an isolated congenital defect that this is not a significant concern. Premature foals, foals with persistent pulmonary hypertension, and foals with dams that have been given prostaglandin inhibitors may be more susceptible to developing a PDA.

The clinical signs depend on the magnitude of the shunting through the PDA, which is determined by its resistance and that of the pulmonary circulation. Physical examination findings (with a left-to-right PDA) include a continuous machinery murmur and thrill, usually loudest over the main pulmonary artery (craniodorsal to the aortic valve area), and bounding arterial pulses. 405

406

Echocardiography reveals pulmonary artery, LA, and LV volume overload. The severity of these findings depends on the magnitude of the shunt. Direct visualization of the PDA is not always possible by two-dimensional echocardiography, because the ductus arteriosus may be hidden from view by the overlying lung. One can best identify ductal flow from the left hemithorax by Doppler echocardiographic examination of the main pulmonary artery. Doppler studies demonstrate continuous high-velocity, turbulent flow, toward the main pulmonary artery. One may detect cardiac enlargement and increased pulmonary vascularity in neonatal foals with a PDA and may identify radiographic evidence of pulmonary edema if the foal has developed CHF. Cardiac catheterization reveals elevated pulmonary artery and capillary wedge pressures and increased pulmonary arterial oxygen saturation. On diagnosing PDA, the clinician should evaluate the foal carefully for other congenital cardiac disease before attempting surgical correction, because complex congenital malformations are the rule in foals with a PDA, and not the exception. Late complications of this lesion include rupture of the pulmonary artery.

* References 146, 149, 155, 158, 233, 318, 502, 519, 524.

8.6.6 TETRALOGY OF FALLOT

The tetralogy of Fallot is one of the more common congenital cardiac anomalies in foals responsible for right-to-left shunting with arterial desaturation and cyanosis.[146,152,157,456] The four lesions are large paramembranous VSD, right ventricular outflow tract obstruction, cranial and rightward (dextro-) positioning of the aorta with overriding of the septal defect, and right ventricular hypertrophy. Outflow obstruction can be caused by subvalvular fibromuscular obstruction, valvular pulmonic stenosis, or hypoplasia of the pulmonary artery. Ventricular hypertrophy is caused by right ventricular outflow obstruction and the large, unrestrictive, VSD that functionally creates a common ventricle. Blood leaves the heart along the path of least resistance, and pulmonary flow depends on the severity of right ventricular outflow tract stenosis. As previously discussed, the degree of cyanosis and severity of clinical signs depends on the volume of blood traversing the lungs. In some horses a PDA is also present (pentalogy of Fallot), and this defect reduces signs by increasing pulmonary flow, left-side heart filling, and systemic arterial hemoglobin saturation.

Affected foals are usually smaller than normal, lethargic, and intolerant of exercise. Cyanosis is most evident after exercise but is variably present at rest. Arterial blood gas analysis demonstrates hypoxemia with normal or reduced P_{CO_2}. Auscultation typically is characterized by a loud systolic murmur over the pulmonic valve area on the left side caused by (sub-)pulmonic stenosis. The S_2 is usually unremarkable. Although polycythemia can be significant, it is usually mild, even when arterial oxygen tensions fall to 50 to 70 mm Hg.

Echocardiographic evaluation is diagnostic and reveals a large, unrestrictive VSD, right ventricular outflow tract obstruction, malalignment and overriding of the aortic root, and right ventricular hypertrophy (see Figure 8-31). One can identify shunting by color Doppler or saline contrast echocardiography. An injection of agitated saline into the jugular vein results in a positive contrast echocardiogram and similar to the color Doppler study discloses the right-to-left or bidirectional shunt. One can use conventional spectral Doppler studies to delineate the shunt (typically bidirectional, low-velocity flow of <2 m/sec) and right ventricular outflow obstruction (high-velocity flow exceeding 4 m/sec).

Although horses possibly may live for a number of years with tetralogy of Fallot, most affected animals are destroyed humanely because of the poor prognosis for life. Owners should not use or breed affected horses if they survive to maturity. One must distinguish tetralogy of Fallot from other causes of cyanotic heart conditions, including tricuspid atresia, pulmonary atresia with VSD, D-transposition of the great vessels, and double-outlet right ventricle with pulmonary stenosis.

8.6.7 PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

Pulmonary atresia with VSD is rare, having been observed most often in Arabian foals.[146,540,545,553] This malformation represents in some ways the exaggerated form of tetralogy of Fallot, with the following findings:

1. Atresia of the right ventricular outlet
2. Hypertrophy of the right ventricle
3. Presence of a large malalignment VSD (in most cases)
4. Partitioning of the fetal truncus arteriosus so unequal that the aorta is greatly dilated and the pulmonary trunk is atretic or severely hypoplastic

Without careful ultrasound studies (or necropsy dissection) of the pulmonary circulation, one may mistake the dilated aorta for a persistent truncus arteriosus, hence the moniker *pseudotruncus arteriosus*. Because of the atretic pulmonary valve, pulmonary blood flow must be derived from a PDA or the aorta. In the latter instance, the systemic collaterals are usually from bronchial arteries. Pulmonary atresia with intact ventricular septum has been diagnosed rarely.[546]

The diagnosis of pulmonary atresia usually is stimulated by clinical findings of cyanosis, cardiac murmur, and stunting in a foal or weanling. Echocardiography confirms the diagnosis. Careful imaging can identify the main lesions: concentric hypertrophy of the right ventricle, unrestrictive VSD, dilated malaligned great vessel (the aorta), and inability to identify the pulmonary valve in the rudimentary right ventricular outflow tract (though a small pouch may be visible). Careful ultrasound examination of the ascending aorta and aortic arch from the right and left sides of the thorax will fail to reveal a normal origin for the pulmonary trunk; however, one usually can find the bifurcation of the pulmonary artery from a cranial imaging position and can document continuous flow into the vessel by pulsed wave Doppler echocardiography. The origin of pulmonary flow is typically from the ductus arteriosus or a large collateral systemic artery.

406

407

8.6.8 TRUNCUS ARTERIOSUS

The failure of the fetal truncus arteriosus to partition into the aorta and pulmonary artery represents a rare anomaly of the equine heart.[154,539] In this condition the fetal truncus never partitions and both ventricles continue to develop, communicating with the truncus arteriosus across a large VSD. Systemic, coronary, and pulmonary arterial flows each arise from the truncus, which is guarded by a truncal valve (which can be incompetent or stenotic). Pulmonary blood flow originates from one or more pulmonary arteries, which arise directly from the truncus arteriosus in one of three general ways (types I, II, and III).

The pathophysiology and clinical findings of this malformation depend largely on the magnitude of pulmonary blood flow. If the pulmonary artery origins are not stenotic and if pulmonary vascular resistance remains low, the clinical condition resembles a left-to-right shunt, except for right-to-left mixing of blood across the VSD. However, the degree of arterial hypoxemia may not be severe, and cyanosis may not be obvious. In such cases, development to maturity is possible provided CHF does not occur from unrestricted pulmonary flow and volume overload of the left ventricle. Conversely, high pulmonary vascular resistance in truncus arteriosus is associated with diminished pulmonary flow, arterial desaturation, and findings more similar to pulmonary atresia as discussed previously.

Clinical examination usually indicates a systolic cardiac murmur. The mucous membranes may be pink or cyanotic. If left-to-right shunting is significant, CHF may occur. With careful ultrasound examination, one can identify the truncus and origin of the pulmonary arteries, thus distinguishing the condition from pulmonary atresia with VSD. Furthermore, in some cases an abnormal truncal valve (with four leaflets) suggests the diagnosis. Management is best accomplished by consultation with a cardiac specialist.

8.6.9 TRICUSPID ATRESIA

Another differential diagnosis for cyanotic heart disease is atresia of the tricuspid valve.[141,146,153,155,553–555] This malformation dictates right-to-left shunting of systemic venous blood at the atrial level. The atrial shunt may be across a true ASD or a patent foramen ovale. Because all venous return must mix in the left atrium, this malformation generally causes significant hypoxemia with cyanosis. Affected foals rarely survive to weanling

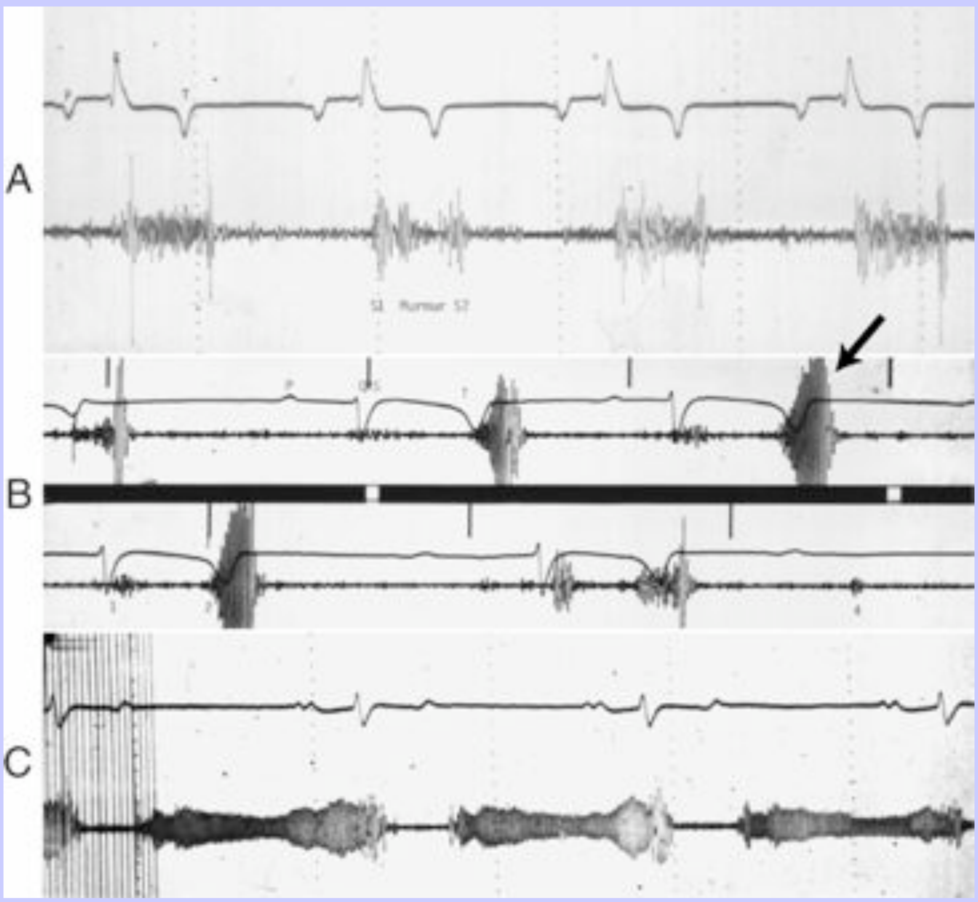
age unless a VSD and functional right ventricular outflow tract exist. Otherwise, pulmonary flow must come from a ductus arteriosus or systemic collaterals (e.g., bronchial arteries). Most foals are stunted, nurse poorly, and exhibit severe exercise intolerance and cyanosis at rest. Arterial oxygen tension can be low (40 to 60 mm Hg). Echocardiography reveals a dilated right atrium and coronary sinus, atretic tricuspid valve, and rudimentary right ventricle (larger if a functional left-to-right shunting VSD is present). One must observe atrial shunting that allows systemic venous return to empty into the left atrium; a VSD may be present. One can verify abnormal flow patterns by contrast or color Doppler echocardiography. Prognosis is grave.

8.7 Acquired Valvular Heart Disease

Healthy cardiac valves maintain normal antegrade flow in the heart and prevent significant regurgitation of blood. Diseased cardiac valves, which can be stenotic or incompetent, limit CO and place an increased workload on the heart. Stenotic valvular lesions in horses are typically congenital and are rare.[115,146,147,158] However, acquired valvular incompetency (also called valvular insufficiency or valvular regurgitation) is common.[*] The majority of valvular diseases in horses are degenerative.[†] Bacterial endocarditis, ruptured chordae tendineae, and inflammatory valvulitis are infrequent causes of valvular disease. Box 8-2 summarizes important causes of valvular dysfunction. Degenerative valvular disease and bacterial endocarditis are the valvular problems most often encountered by the equine practitioner and are the focus of this section.

The clinical significance of a valvular lesion depends largely on the severity of regurgitation across the valve. Many horses clearly adapt to trivial or mild valvular regurgitation with no apparent effect on performance. The severity of valvular regurgitation is related to the cross-sectional area of the regurgitant orifice, the pressure gradient driving blood across the valve, and the time allowed for regurgitation. Regardless of the volume, the movement of blood from a high to low pressure chamber is associated with a high-velocity jet proportional to the pressure drop measured from source to sink. The production of high-velocity jets leads to disturbed flow (with 407
408
turbulence) and in many cases to a cardiac murmur, the hallmark clinical feature of valvular heart disease (Figure 8-32).

Figure 8-32 Phonocardiograms of cardiac murmurs caused by valvular heart disease. **A,** A holosystolic murmur of mitral regurgitation in a horse with chronic valvular degeneration. **B,** A variable, late systolic murmur of mitral regurgitation related to mitral valve prolapse. The murmur has a crescendo and peaks at end systole *(arrow)*. Heart sounds are indicated. The murmur obscures the second sound. **C,** A holodiastolic, vibratory murmur of aortic regurgitation with presystolic accentuation. The accentuation probably is related to atrial contraction, altered ventricular volume and pressure, and an incremental increase in regurgitant volume.



One may diagnose valvular incompetency by auscultation or with Doppler echocardiography.[119,430,437] Auscultation is the most clinically important method for identifying clinically significant valvular disease. Doppler studies are so sensitive for identification of valvular regurgitation that color Doppler imaging represents the clinical gold standard for identifying valvular dysfunction. Many horses with normal auscultation findings demonstrate

varying degrees of valvular regurgitation by Doppler examination, however, and the point deserves emphasis. Most cardiologists consider these silent valvular leaks as normal,[454] especially those observed on the right side of the heart. No doubt some cases of silent regurgitation do represent the earliest signs of degenerative valvular disease, but clinical benefit to screening horses by Doppler is not established, and the approach is not practical or necessarily predictive of future outcome.

Although examiners usually discount silent regurgitation, one also must place the clinical significance of *audible* valvular regurgitation in context. For example, examination of high-performance athletes demonstrates murmurs of tricuspid, mitral, or aortic valvular insufficiency in many of these horses. These findings are readily verifiable by Doppler imaging. In one study of 2-year-olds,[437] the prevalence of tricuspid and mitral regurgitant murmurs increased significantly over a 9-month training period to an incidence of 25.5% and 21.8%, respectively. The causes of these changes and the interpretation of these findings are problematic, especially when referenced to the clinical benchmark of normal. Possibly the high-level training induces changes in ventricular geometry or in valvular thickness related to cardiovascular work, elevations of blood pressure during training, or other factors. Nevertheless, whether these murmurs are actually normal or not, clearly one must interpret the *clinical significance* of a regurgitant murmur in a horse with caution and certainly in light of training, performance history, and clinical findings.

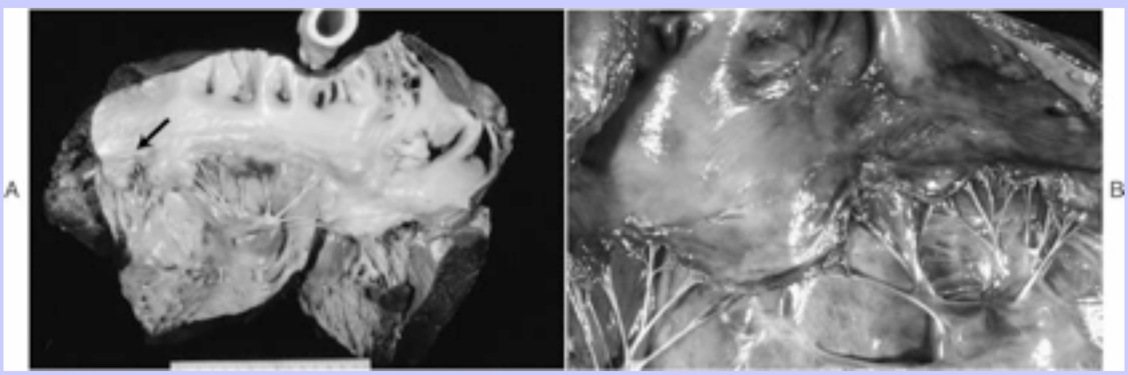
Assessing the significance of a cardiac murmur involves scrutiny of the work history, the physical examination findings, and the results of echocardiography. Other studies such as electrocardiography and exercise testing provide further information by which to judge the importance of a murmur. As a general rule, significant regurgitant murmurs tend to be loud and long. However, the intensity of an insufficiency murmur is related not only to the regurgitant volume but also to the driving pressures of blood and the physical characteristics of the thorax. Therefore although the examiner can grade the intensity of a heart murmur (see the foregoing discussion in this chapter), grading the severity of regurgitation by auscultation alone is not possible. Loud murmurs may be associated with regurgitant volumes that are inconsequential to an individual horse, especially when the murmur is high-pitched, vibratory, or musical. Thus although clinically significant valvular heart disease is best *identified* by auscultation (see Table 8-2), one must assess the *clinical relevance* of a valvular incompetency in other ways.[*] This approach is emphasized as the commonly detected acquired valvular conditions are considered in this section.

8.7.1 MITRAL REGURGITATION

MR is one of the more common murmurs detected in horses. The etiopathologic basis of mitral valve incompetency can be any of the following: degenerative thickening, idiopathic disease, prolapse of the valve, ruptured chordae tendineae, bacterial endocarditis, noninfective valvulitis, primary or ischemic myocardial 408
disease, and congenital malformation of the valve (Figures 8-33 and 8-34; see also Tables 8-2 and 8-3).[*] 409
Degenerative, fibrotic thickening of the mitral valve has been observed at necropsy in mature horses and is probably the basis for most cases of mild to moderate MR, including those with normal two-dimensional echocardiographic imaging. The basis of mitral valve prolapse is uncertain but could involve connective tissue disease of the leaflets, stretched chordae tendineae, minor chordal ruptures, or ischemic injury to a papillary muscle. Ruptured mitral valve chordae tendineae with flail mitral leaflet can occur in animals of any age, including foals. Chordal ruptures, which often involve the accessory mitral cusps, may lead to severe MR with fulminant CHF. Necropsy findings often show degenerative thickening of the ruptured strand; endocarditis rarely is involved. The mitral valve is one of the main valves affected in bacterial endocarditis of horses. Although uncommon, mitral valve infection can lead to ulceration, vegetation, or chordal injury and substantial MR (see the following discussion). The authors have observed MR caused by severe mitral scarring and thickening in weanlings and young horses. The cause of these lesions is unknown, but the nonsuppurative valvulitis identified

might be related to an immune-mediated process. Cardiomyopathy, myocarditis, or myocardial infarction can lead to valvular insufficiency through dilation of the mitral annulus or loss of papillary muscle support.

Figure 8-33 Postmortem lesions of mitral regurgitation (see also Figure 8-40, A). **A,** The opened left ventricle and left atrium are viewed from the caudal perspective. Mild mitral valve fibrosis has led to thickening and incompetency. A jet lesion is evident *(arrow)* as well as modest left-sided heart enlargement. **B,** Chronic suppurative valvulitis caused by chronic endocarditis has led to scarring, thickening, and distortion of the mitral valve. This horse developed severe left-sided congestive heart failure. Noninfective valvulitis also is recognized sporadically in horses, particularly in younger animals.

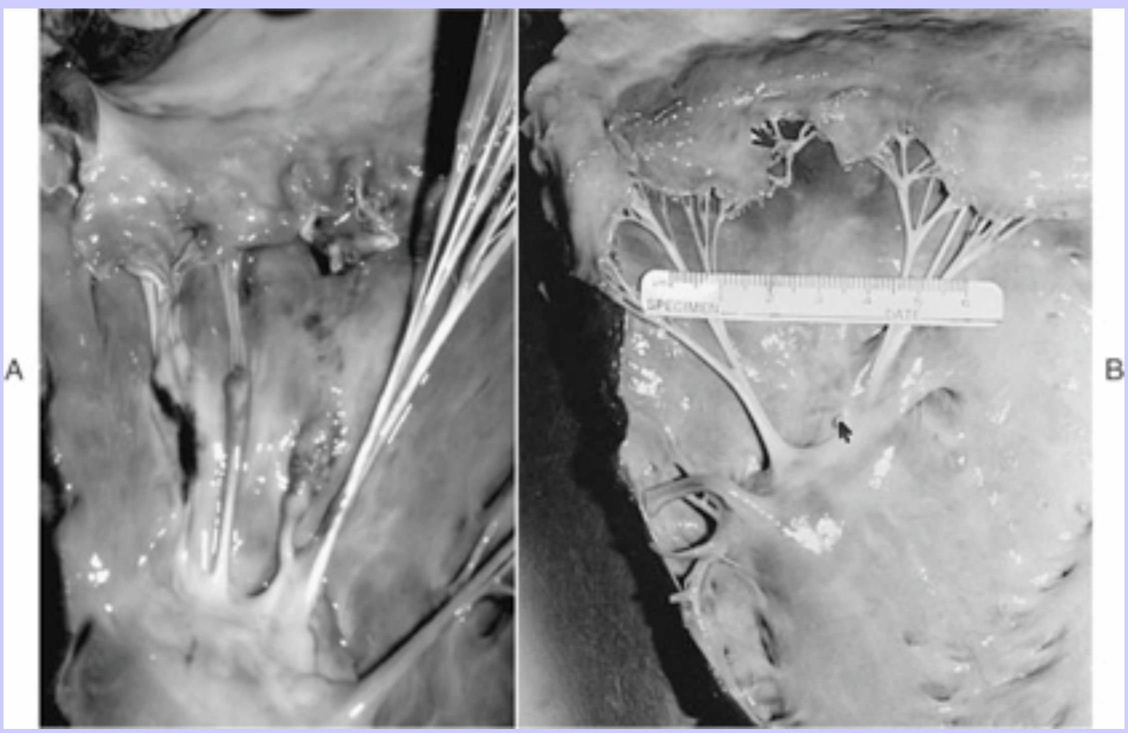


The *clinical presentation* of the horse with MR varies. MR is often an incidental finding detected during a routine examination. In other situations, one may identify the MR in a horse with suboptimal performance or overt clinical signs of heart failure. As indicated previously, soft murmurs of MR are common in high-performance horses.[437] When MR is only mild to moderate, significant LA dilation and LV volume overload are not evident, and the horse often performs satisfactorily. With moderate to severe MR, clinical signs are likely to include poor performance, exercise-induced pulmonary hemorrhage, or overt CHF. Tolerance of the lesion depends largely on whether the horse is used for vigorous work. Some horses with MR also develop atrial fibrillation, which can impair CO further. On identifying a murmur of MR within the setting of fever, weight loss, polyarthritis, or systemic inflammation, one should consider bacterial endocarditis. MR related to chordal rupture is a rare but well-recognized cause of severe CHF with fulminating pulmonary edema (see Figure 8-10). Chronic, hemodynamically significant MR from any cause can lead to pulmonary hypertension, atrial fibrillation, and biventricular CHF, with clinical signs of right-sided CHF dominating the clinical presentation (see the previous discussion in this chapter).[48,102]

The *physical examination* of the horse with MR typically reveals a grade 2 to 5 out of 6 holosystolic murmur. The murmur is most intense at or dorsal to the palpable left apical impulse and over the mitral valve area (see Figures 8-7 and 8-32). Often the murmur is loud at the aortic valve, probably related to the proximity of the septal mitral leaflet to the aortic valve or to cranial projection of the regurgitant jet. Loud MR murmurs often 409 410

project dorsally and to the right. The typical murmur of MR is long (holosystolic or pansystolic), extending into the S_2,[38] and may cause the listener to misinterpret S_3 as S_2, thus preventing a full appreciation of the significance of the murmur. When S_3 is loud, the clinician should suspect significant volume overload or increased LV diastolic pressure. Because many horses with MR also have concomitant TR, one may need echocardiographic examination and Doppler studies to differentiate bilateral atrioventricular valve insufficiency from isolated MR with radiation to the right. Finally, the murmur of MR can be modified by atrial fibrillation or premature beats.

Figure 8-34 Rupture of the mitral valve chordae tendineae. **A,** Acute rupture of a chorda tendinea in a horse with lymphocytic plasmacytic valvulitis. The flail mitral cusp actually has twisted because of loss of support. The ventral portion of the tear is obvious adjacent to intact chords. **B,** Chronic rupture of a chorda tendinea in a horse. The contraction of the scarred segments *(arrow)* is notable.

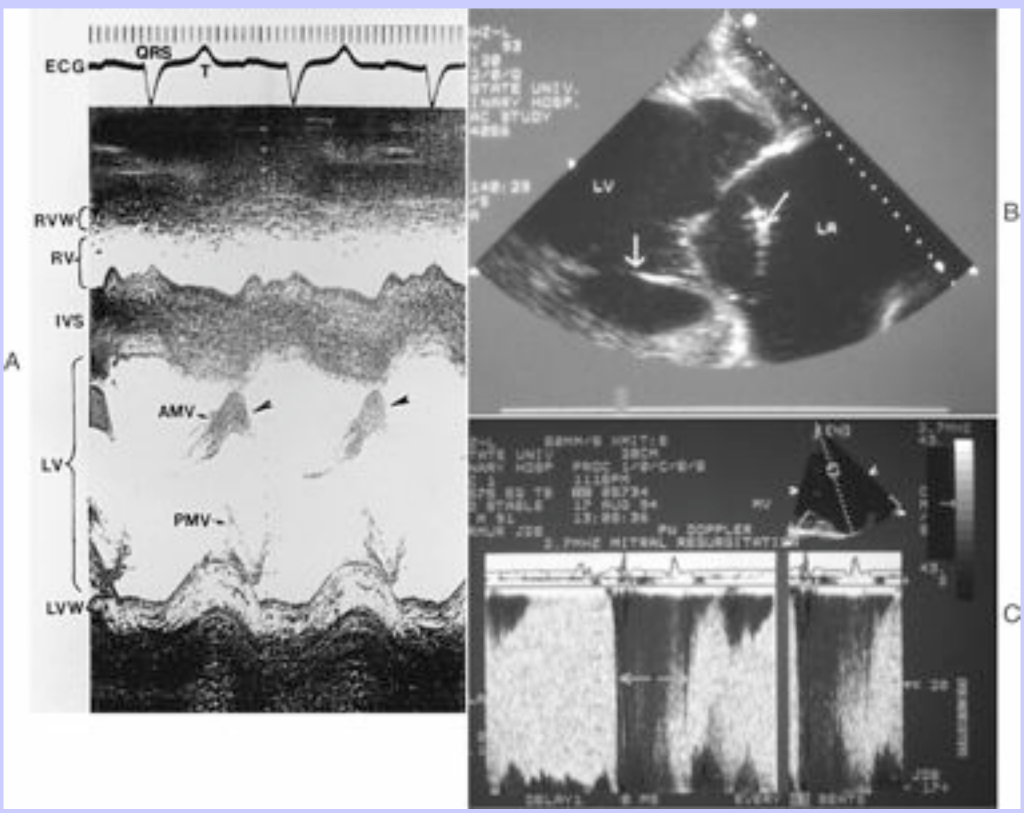


Two variants of holosystolic MR murmur are the protomesosystolic decrescendo murmur and the mid to late systolic crescendo murmur (see Figure 8-32). One may detect a decrescendo murmur with mild MR because coaptation of the leaflets may occur as the ventricular volume decreases during late systole. One easily may confuse this type of murmur with a functional ejection murmur, unless the point of maximal murmur intensity is centered near the left apex. Conversely, severe MR with CHF conceivably could cause a decrescendo murmur because atrial and ventricular pressures may equilibrate in late systole. However, such a murmur is not a common finding even in severe MR. The other variant of MR is the mid to late systolic crescendo murmur (see Figure 8-32, *B*). Presumably this murmur is caused by mitral valve prolapse. Whereas LV dilation worsens the

typical murmur of MR, the murmur of mitral valve prolapse starts *after* the left ventricle has begun ejection. Decreasing LV volume allows a mitral cusp to prolapse causing midsystolic regurgitation that builds through S_2. The resultant murmur can be harsh or musical, and the novice often confuses this flow event with an early diastolic murmur.

Echocardiography and Doppler examinations play a pivotal role in assessing the horse with MR[*] (Figure 8-35) and are indicated to examine the valve anatomy; estimate the severity of MR; measure the size of the atria, ventricles, and great vessels; and quantify LV systolic function. The underlying cause of MR may be obvious from the echocardiographic examination. Mild to moderate valvular thickening, although admittedly subjective, is compatible with degeneration or nonbacterial valvulitis. Prolapse of the mitral valve cusps has been observed in horses with MR, but the limits of normal prolapse require further definition. Lesions caused by vegetative endocarditis cause the valves to appear irregularly thickened or shortened. In cases of acute endocarditis, one 410
usually finds evidence of valve thrombus, and a high-frame rate real-time examination may show oscillation of 411
this tissue. In chronic endocarditis, the valve may be more echodense, or even appear calcified. Chordal rupture is recognizable by observing chaotic flutter of a mitral structure (a flail leaflet), prolapse of a large portion of the valve into the atrium, or the chordal remnant (it usually is contracted) flipping into the atrium during systole (see Figure 8-35). High-frequency systolic vibrations of the mitral valve may be visible on the M-mode study in horses with a musical murmur of MR. Pulsed or continuous wave or color Doppler studies can identify the mitral regurgitant jet. In most horses one can perform this examination best from the left cardiac windows. High-velocity or turbulent jets may be difficult to find without a complete and thorough examination of the mitral valve that involves multiple image planes. When color flow Doppler demonstrates a wide *origin* of the regurgitant jet and a pattern of diffuse distribution of turbulence deep into the left atrium, the likelihood of hemodynamically significant MR is greater. Quantitation of cardiac size is instrumental in assessing severity. With severe MR and LV volume overload comes rounding of the LV apex and increased end-diastolic dimension (see Table 8-5). Global LV function may appear normal to exuberant because the incompetent valve decreases ventricular afterload (see Figure 8-5, *B*). However, when MR is severe and chronic or if the underlying basis for MR is cardiomyopathy, the ventricular shortening fraction is decreased. The left atrium often assumes a more circular, almost turgid, appearance when MR is hemodynamically significant, and the two-dimensional 411
echocardiographic measure of internal atrial dimension often exceeds 13.5 to 14 cm. With acute or chronic MR, the lobar and main pulmonary artery may be dilated as a result of pulmonary hypertension, presumably related to increased LA pressure, interstitial lung edema, pulmonary vascular remodeling, or other factors. 412

Figure 8-35 Echocardiograms recorded from horses with mitral regurgitation. **A,** M-mode study demonstrating significant thickening of the anterior mitral valve *(AMV)* leaflet *(arrows)*. This would be compatible with endocarditis or severe valvulitis. (*RVW,* Right ventricular wall; *RV,* right ventricle; *IVS,* intraventricular septum; *LV,* left ventricle; *LVW,* left ventricular wall.) **B,** Flail mitral leaflet *(right arrow)* in a horse with multiple chordae ruptures. The prolapsed portion of the mitral valve forms a curved echodense line in the dilated left atrium, whereas the other valve portions are to the left of this echocardiogram. A normal chord is evident *(left arrow)*. **C,** Pulsed wave Doppler study recorded from the left atrium demonstrating a turbulent, high-velocity, aliased systolic jet of mitral regurgitation in a Thoroughbred horse. The duration of the event is shown *(arrows)*.



The *prognosis* for horses with MR varies and, as discussed previously, is related to clinical findings, work history, and results of echocardiographic studies. One should consider abnormalities observed during

echocardiography—including lesions of the mitral valve leaflets, the degree of LA and LV volume overloading, global LV function, and Doppler findings—when formulating the prognosis. Certainly, when MR is associated with CHF, atrial fibrillation, endocarditis, chordal rupture, significant cardiomegaly, severe valvular thickening, dilated cardiomyopathy, or pulmonary hypertension, the prognosis for life or performance is poor. The detection of pulmonary artery dilation indicates significant pulmonary hypertension and the possibility of pulmonary artery rupture; therefore such a horse should not be ridden or driven because of the low but concrete risk of sudden death. Fortunately, the majority of horses with MR appear to perform well, indicating that MR in most cases is not clinically important. Whether progressive exercise intolerance will develop in a particular case depends on the use of the horse and on the progression of the underlying lesion. Generally, when valve degeneration causes MR and the heart size is normal, the progression is gradual, the prognosis for life is favorable, and the horse maintains performance. When MR is detected in an untrained colt or filly, the prognosis is less encouraging. The presence of even mild to moderate cardiac dilation in a case of MR recommends a more guarded prognosis, though this is made best by serial examinations. The significance of mild MR in the high performance horse or racehorse is uncertain. In some animals, treadmill exercise is normal, whereas others may demonstrate a higher heart rate for a given level of work than might otherwise be expected. The latter finding may suggest a cardiac limitation to performance.

Regardless of cause or severity of the condition, the horse diagnosed with MR merits follow-up examinations to evaluate progression of the hemodynamic burden and to detect the development of CHF, pulmonary hypertension, or cardiac arrhythmias. Treatment of MR involves management of complications such as heart failure, endocarditis, or arrhythmias. These topics are covered elsewhere in this chapter.

8.7.2 AORTIC REGURGITATION

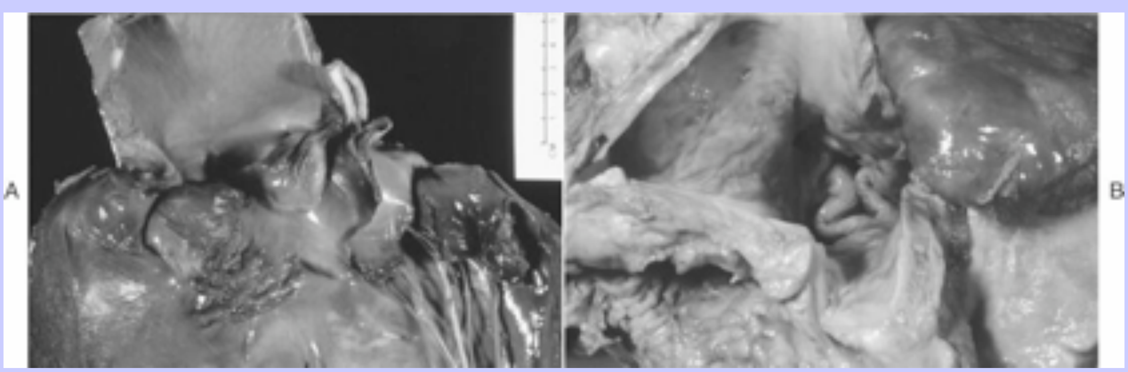
Aortic regurgitation (AR) is a common valvular insufficiency. Degeneration of the aortic valve is by far the most common reason for AR, although other potential causes include idiopathic prolapse, bacterial endocarditis, congenital valvular disease, VSD (see the previous discussion in this chapter), noninfective valvulitis, and ruptured aortic sinus aneurysm (see Tables 8-2 and 8-3).[*] The degenerative nodular lesions and fibrous bands responsible for AR in older horses have been well described by Bishop, Cole, and Smetzer[5] (Figure 8-36). Prolapse of the aortic valve is a common echocardiographic finding and probably represents another variant of connective tissue degeneration. Small fenestrations of the valve have been identified at necropsy but have uncertain clinical significance.

In most horses AR is an incidental finding detected during a routine physical, prepurchase, or insurance examination. Most horses with this murmur are older than 10 years of age, and the murmur is common in aged horses, a testament to the degenerative nature of the lesion. Careful auscultation in a quiet area may help one identify a soft diastolic murmur in a younger horse. Silent AR also may be considered physiologic, and identifying a small jet of AR by Doppler studies in horses with no identifiable diastolic murmur is common.[454] When one identifies a loud murmur of AR in a younger animal, one should consider other causes. Poor

performance is an infrequent presenting complaint in horses with AR, because most horses continue at their prior performance level, provided that no other clinical or cardiac abnormalities are present. Intermittent fevers, weight loss, or lameness should prompt consideration of endocarditis. CHF occurs infrequently with isolated AR but may develop in the horses with combined AR, mitral valvular disease, or atrial fibrillation. Statistical evidence from Marr and colleagues indicates that in the United Kingdom, older horses with AR have a shorter survival and are more prone to developing CHF and ventricular arrhythmias or dying suddenly.

One can identify clinically important AR by cardiac auscultation, which reveals a holodiastolic murmur, with the point of maximal intensity over the aortic valve area and good radiation to the right and toward the left cardiac apex. The murmur may vary greatly in intensity. The quality is typically harsh and decrescendo with a blowing nature, but presystolic accentuation may occur (see Figure 8-32, *C*). In some cases the murmur is vibratory, musical, cooing, or buzzing. One can palpate a precordial thrill over the aortic valve area when the murmur is loud. A variant of the typical AR murmur is that associated with rupture of the right aortic sinus into a cardiac 412
chamber or into the ventricular septum. In this instance the holodiastolic murmur may be louder on the right side 413
of the thorax. However, in the majority of horses with an aortic-cardiac fistula, a continuous machinery murmur is audible. Atrial fibrillation, atrial premature depolarizations, and ventricular extrasystoles infrequently have been associated with AR. The quality of the arterial pulses is a good indicator of the severity of the isolated AR.[128] Bounding arterial pulses indicate significant LV volume overload and moderate to severe AR. A systolic ejection murmur is often present, particularly when the regurgitant volume is large, and is explained by ejection of a large stroke volume across the aortic valve. A point of emphasis is that no evidence indicates that the degenerative aortic valve is anatomically stenotic.

Figure 8-36 Postmortem lesions of aortic regurgitation (see also Figure 8-40, *B*). **A,** A segment of the left ventricular outflow tract and the ascending aorta. Linear bands are evident on the two valves shown, and a large jet lesion also is visible below the valves. The lesion is typical in aged horses. **B,** The aortic valve viewed from the ascending aorta. Noninfective valvulitis and scarring have caused severe thickening.



A complete echocardiographic examination including Doppler echocardiography is useful for further evaluation of horses with AR, particularly when the arterial pulse is abnormal or cardiac-related clinical signs are suspected. One may identify a number of echocardiographic abnormalities in horses with AR (Figure 8-37).[*] Subjective

thickening of the aortic valve leaflets and prolapse of one or more leaflets are common observations. In cases of endocarditis, the leaflets may appear thickened, irregular, and more highly echogenic. The valve may appear to oscillate if a fresh thrombus is within the vegetation. Fenestrations of the aortic valve leaflets, flail aortic leaflet, aortic sinus aneurysm, and aortic root prolapse into a VSD are detected rarely. Dilation of the aortic root (exceeding 10 cm) may occur in some horses with AR. The flow disturbance of AR may be evident from Doppler or M-mode studies. The Doppler examination shows one or more central or eccentric diastolic jets of AR. One can verify the timing of the flow disturbance by spectral studies or color M-mode. The traditional M-mode study in horses with AR often reveals high-frequency diastolic vibrations of the septal mitral valve leaflet related to the high-velocity regurgitant jet entering the LV outflow tract. One also may detect similar vibrations on the intraventricular septum when the regurgitant jet is directed cranially. High-frequency fluttering of the aortic valve leaflets or aortic walls may be detectable especially in horses with musical murmurs. Increased mitral valve E-point to septal separation may result from the regurgitant jet impinging on the valve or may indicate cardiac dilation and failure. In the latter case, other markers of severe insufficiency will be evident, including ventricular dilation; rounding of the LV apex; a strong, long, and wide origin Doppler signal of AR; and a short pressure half-time. An exaggerated or swinging septal motion represents another subjective observation of volume overload on real-time two-dimensional echocardiographic examination. Premature (presystolic) mitral closure is another sign of severe AR indicating elevated ventricular end-diastolic pressure. The LV volume overload that develops with AR leads to increased ventricular internal diameter at end-diastole, increased shortening fraction, and decreased free wall thickness. If myocardial failure develops, the end-systolic dimension may be increased, despite normal shortening fraction.

The clinical significance and prognosis of AR is based most accurately on the history, physical examination, and echocardiogram. Because most cases of AR are associated with a slow degeneration of the aortic valve leaflets, 413
and this occurs in older horses without other cardiac problems, the prognosis for life and performance is usually 414
good. Such animals typically have minimal echocardiographic abnormalities or only mild echocardiographic signs of volume overload. The findings of flail aortic valve leaflet, endocarditis, or echo markers of moderate to severe volume overload or myocardial failure indicate a poor prognosis for life and performance. One should obtain an exercising ECG in performance horses with significant aortic regurgitation to determine if the horse remains safe to ride. One also should consider a Holter ECG as a potential test in older, valuable animals because of the statistical relationship between AR, ventricular extrasystoles, and sudden death. Follow-up clinical and echocardiographic examinations are indicated for the horse with moderate to severe AR. One should anticipate the development of secondary MR, atrial fibrillation, ventricular arrhythmias, CHF, or sudden death in horses with severe volume overload.

Figure 8-37 Echocardiograms recorded from horses with aortic regurgitation (see also Figure 8-20, *C*). **A,** Aortic valve prolapse *(arrow)* in a 12-year-old Standardbred gelding. **B,** A well-circumscribed, echodense “bead” on the noncoronary cusp of the aortic valve in a 2-year-old Standardbred colt may represent a congenital or acquired lesion. This short-axis image plane is recorded across the base of the heart. **C,** Continuous wave Doppler recording from the same horse as in **A** demonstrates a turbulent diastolic signal that ends at the QRS complex *(arrow)*.

8.7.3 TRICUSPID REGURGITATION

TR may be the most frequently detected of flow disturbances and murmurs in the horse,[*] although virtually nothing is written about the etiopathogenesis of this condition. The anatomic basis of tricuspid valve incompetency can be any of the following lesions: idiopathic, degenerative thickening, prolapse, noninfective tricuspid valvulitis, bacterial endocarditis, pulmonary hypertension (including left-sided failure), ruptured

chordae tendineae, myocardial disease with secondary cardiomegaly, chronic tachyarrhythmia, and congenital malformation of the valve. TR is common in horses of racing age[437]; however, the anatomic correlation to this incompetency is uncertain. Degenerative, fibrotic thickening of the tricuspid valve in mature horses may lead to mild to moderate TR. Compared with the mitral condition, ruptured tricuspid valve chordae tendineae are uncommon[556] and better tolerated unless associated with endocarditis. Bacteria can infect the tricuspid valve, and in some cases infection occurs following an injudicious or septic jugular venipuncture or catheterization. Pulmonary hypertension, cardiomyopathy, and myocarditis can lead to secondary dilation of the tricuspid annulus or alteration of papillary muscle support, permitting valvular insufficiency. Tricuspid malformation does occur but seems more commonly associated with stenosis or atresia of the valve[*] (see the previous discussion in this chapter).

414

415

A soft, grade 2 to 3 out of 6 systolic murmur of TR is most often an incidental finding detected during a routine examination. The murmur becomes more problematic when it is loud or is identified in a horse that is performing poorly. Many horses with TR race well; therefore the clinician first should exclude other likely reasons for poor performance before incriminating the tricuspid valve. Of course, if chronic hemodynamically significant TR has developed, then peak work effort suffers and even right-sided CHF may develop. The latter situation is not common unless the TR follows pulmonary hypertension or bacterial endocarditis or unless severe TR is associated with atrial fibrillation. Prominent jugular pulses (giant c-v waves) are typical of horses with TR associated with CHF.

Auscultation of the horse with TR typically reveals a grade 2 to 5 out of 6 holosystolic murmur with the point of maximal intensity over the right hemithorax at the tricuspid valve area (see Figure 8-8; Tables 8-2 and 8-3). The murmur can be holosystolic, decrescendo, or mid to late systolic. Although the timing and intensity at times may remind the examiner of a functional murmur, the location of greatest murmur intensity argues against that possibility. The murmur usually radiates dorsally and if loud to the extreme left cranioventral thorax. The intensity of the TR murmur in many cases does seem to correlate to the regurgitant volume and definitely depends on the pulmonary artery and RV systolic pressure. Thus a grade 4 or louder murmur is anticipated with moderate to severe TR or when TR is related to pulmonary hypertension. Atrial fibrillation or atrial premature beats are present in some horses with TR, particularly when the right atrium is dilated or the regurgitant jet is large.

Echocardiography with Doppler studies are useful in assessing TR (Figure 8-38). One typically performs examinations of the tricuspid valve from the right side of the thorax, because the tricuspid valve and RV inlet are closer to the right thoracic wall; however, an extreme left cranial transducer location also can be successful for examining tricuspid flow. Because a number of potential reasons for tricuspid incompetency exist, one must direct careful attention to the valve and its support apparatus, the size of the pulmonary artery, and the left side of the heart. Usually one can diagnose or exclude valve thickening, prolapse, vegetations, chordal rupture, regurgitation following RV dilation, and pulmonary hypertension with careful imaging. However, in most cases one cannot detect a clear-cut lesion of the tricuspid valve leaflet. As with MR, moderate to severe TR leads to RA and RV volume overload; however, quantifying these chamber volumes is more difficult because of their complex geometry. Doppler studies can identify the tricuspid regurgitant jet. In trivial or silent TR, this jet is typically narrow at the origin and directed at the aorta. However, when the jet is wide at its origin or projects centrally or laterally into the right atrium, cardiomegaly is more likely to be present and one should examine the heart carefully. One can estimate the RV (and pulmonary artery) systolic pressure by faithfully recording the peak jet velocity. Estimation requires the examiner to align the continuous wave Doppler cursor to regurgitant flow. When the jet velocity is less than 2.5 m/sec, pulmonary hypertension is not present. Jets exceeding 3.2 to 3.4 m/sec indicate pulmonary hypertension (provided that ventricular outflow obstruction or VSD is not present).

The identification of pulmonary hypertension should prompt careful examination of the left side of the heart, because the main cardiac lesion may be centered over the mitral valve, aortic valve, or LV cavity.

The prognosis for horses with TR is generally favorable. Generally a soft murmur of TR in a trained athlete is disregarded as clinically insignificant; although defining such a disturbance as functional would be imprecise in the authors' opinion. The presence of TR is more likely to cause concern if right-sided cardiomegaly, pulmonary hypertension, or atrial fibrillation is evident. Abnormalities detected during echocardiography of the tricuspid valve leaflets may be instructive because the visualization of a vegetation or chordal rupture would indicate a poor prognosis for performance and a guarded prognosis for life. The width of the regurgitant jet at its origin, recent performance history, and results of exercise testing are useful in developing a prognosis for life and future work. Knowing whether exercise and the associated pulmonary hypertension worsen the degree of TR in horses over time would be interesting, and the increased use of exercise testing and postexercise echocardiography may provide answers to this question. When TR is judged to be moderate or severe, periodic reexaminations are indicated to follow the progression of the lesion and to detect cardiomegaly or cardiac arrhythmias if they develop.

Figure 8-38 Echocardiograms from horses with tricuspid regurgitation (see also Figure 8-23, *C*). **A,** Two-dimensional echocardiogram demonstrating probable valve thickening, significant right atrial distention, and spontaneous right atrial contrast in a horse with severe tricuspid regurgitation, atrial fibrillation, and congestive heart failure (1-cm calibrations at the left of the sector; *LVOT,* left ventricular outflow tract). **B,** Continuous wave Doppler recording of a high-velocity tricuspid regurgitation jet from a horse with tricuspid regurgitation caused by pulmonary artery obstruction caused by a mass lesion. The high velocity of regurgitation, greater than 3.6 m/sec, indicates that elevated right ventricular pressure is driving the regurgitant jet. In this case the high pressure is caused by supravalvular pulmonary stenosis caused by the tumor. Tricuspid regurgitation jets associated with normal right ventricular pressures are typically less than 2.6 m/sec.

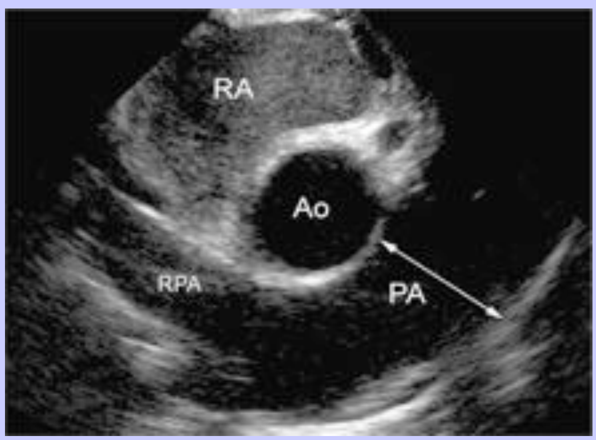
8.7.4 PULMONARY INSUFFICIENCY

One often can detect trivial and clinically silent physiologic pulmonic insufficiency by Doppler studies; however, this is a normal finding.[120,139,205,430] Clinically significant pulmonic insufficiency is uncommon and occurs most frequently with pulmonary hypertension associated with left-sided heart failure. Bacterial endocarditis and congenital abnormalities of the valve leaflets (bicuspid or quadricuspid) occur, but these are rare causes of pulmonary insufficiency.[125] A rare cause of this condition is rupture of the pulmonary valve.[127]

Murmurs of pulmonic regurgitation are usually undetectable unless the regurgitant volume is large or is driven by pulmonary hypertension; however, one can identify the flow disturbance using pulsed wave and color flow Doppler echocardiography. One may detect dilation of the pulmonary artery with echocardiography when pulmonary hypertension causes pulmonic insufficiency (Figure 8-39).

When severe pulmonic regurgitation does develop, it generally results from left-sided heart failure and is accompanied by clinical signs of biventricular failure, including increased respiratory rate and effort. Signs of right-sided CHF result from pulmonary hypertension, pulmonic regurgitation, RV volume overload, and TR. If 416
one detects a murmur of pulmonic regurgitation, the murmur is usually holodiastolic and decrescendo, with the 417
point of maximal intensity at the pulmonic valve area, radiating toward the right cardiac apex. The prognosis for life and performance is usually poor in these cases.

The cause was pulmonary hypertension following left-sided congestive heart failure. *RA,* Right atrium (with spontaneous contrast in cavity); *RPA,* right branch of the pulmonary artery.



8.7.5 BACTERIAL ENDOCARDITIS

Bacterial endocarditis is caused by bacterial invasion of the heart valves or endocardium. Endocarditis is not common in horses but occurs sporadically in most populations.[*] The infection may affect horses of any age, although the pathogenesis may differ in younger animals or in those that are immunosuppressed. In one report, the mean age of affected horses was 2.1 years.[442] Numerous bacteria have been associated with bacterial endocarditis. The offending microorganism likely depends on the environment, portal of entry (e.g., gastrointestinal tract, skin, lung, oral cavity, joint, surgical wound, or intravenous catheter), and the effects of prior antibiotic therapy that may select for resistant strains. *Streptococcus* sp., *Actinobacillus equuli,* and *Pasteurella* sp. have been isolated most frequently. *Rhodococcus equi, Candida parapsilosis, Erysipelothrix rhusiopathiae,* meningococci, *Staphylococcus aureus,* and other organisms including aspergillus also have been isolated.

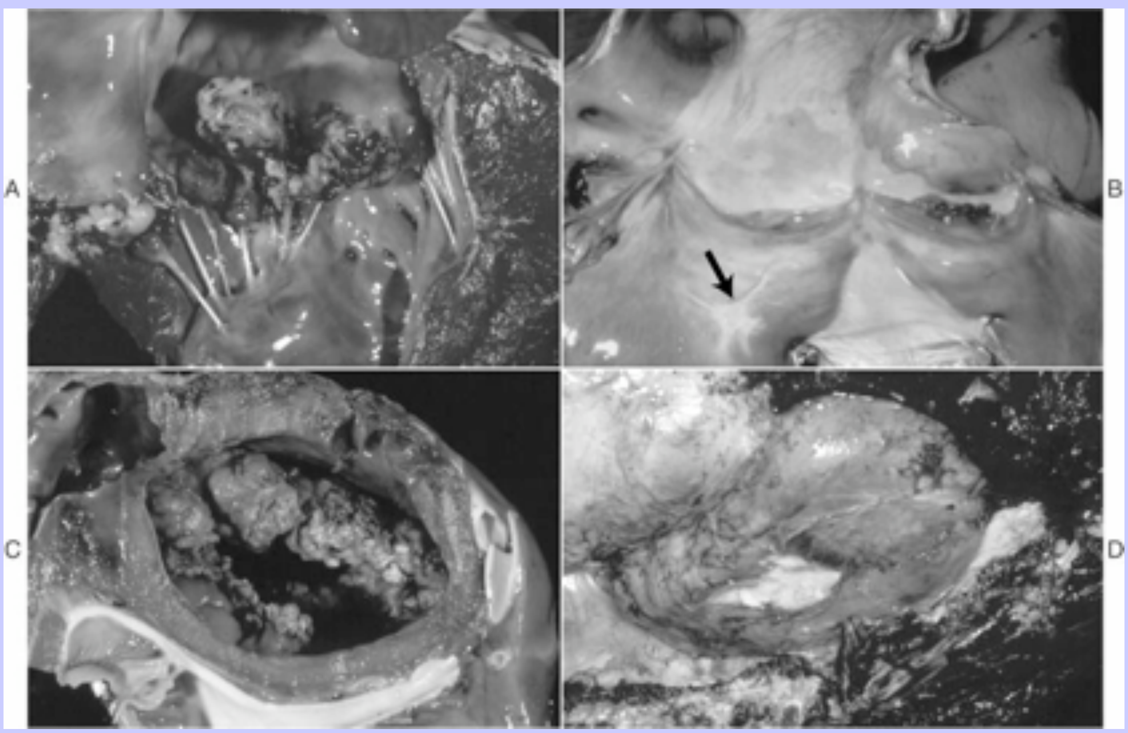
The pathogenesis involves bacterial invasion from the bloodstream and colonization of the heart valve or endocardial surfaces. Bacteremia is a prerequisite for development of this condition. Direct invasion of a previously normal valve by virulent bacteria, or in the context of overwhelming sepsis, represents the most likely pathogenic mechanism involved in foals with bacterial endocarditis. Disruption of the endocardial surface by jet lesions associated with congenital intracardiac shunts also may predispose horses to endocarditis, although this mechanism is not well established in horses. Preexisting valvular heart disease with endocardial changes or high-velocity jets may represent risk factors for bacterial colonization in older horses, but again this is not established. The most common sites of bacterial endocarditis are the aortic and mitral valves, although endocarditis lesions have been reported on all cardiac valves. Mural endocarditis lesions also have been reported but occur much less frequently. The combination of bacterial injury, exposure of valve collagen, thrombosis, and host leukocyte response contributes to the development of a vegetation (Figure 8-40), which consists microscopically of bacteria, platelets, fibrin, leukocytes, and varying degrees of granulation or fibrosis. Bacteria may not be evident at necropsy, especially if antimicrobial therapy has sterilized the vegetation.

The pathophysiology of endocarditis in horses is probably similar to that in other species. A host response, as well as the primary cardiac lesions, contributes to the morbidity of this disease. Cardiac manifestations include valvular injury leading to regurgitation, chordal rupture, or rarely to stenosis; secondary cardiomegaly; myocarditis from extension of the infection or through coronary embolization; myocardial infarction if emboli are shed to the coronary arteries; arrhythmias from cardiomegaly or myocarditis; and myocardial depression from bacteremia. Recurrent or chronic bacteremia, and hence fever, is characteristic of endocarditis. Metastatic infection, distant thrombosis and infarction, and immune-mediated host responses can occur. Distant infection or immune complex disease can lead to multisystemic clinical signs, including arthritis, osteomyelitis, vasculitis, or nephritis. Right-sided thrombi can lead to pulmonary thrombi, and or abscessation of the lungs (see Figure 8-40).[125,559]

Clinical features of endocarditis vary.[442] Affected horses usually have a history of intermittent fever, weight loss, depression, anorexia, lethargy, and often intermittent lameness (Figure 8-41). A predisposing condition or a concurrent infection may be evident, including jugular vein thrombophlebitis, strangles, septic joint, or an abscess. Most horses have no history of previous illness and no evidence of concurrent infection. The physical examination often reveals fever, and some horses may be tachypneic. The fever is often intermittent. One detects murmurs of mitral or aortic valvular insufficiency most commonly; those of TR are less common. One must differentiate systolic murmurs caused by valve destruction from the physiologic flow murmurs that are so often audible in febrile horses (see Table 8-2). One also may detect murmurs of valvular stenosis with bacterial endocarditis, but these occur infrequently.[125] Some horses with bacterial endocarditis have no auscultable murmur initially. The quality or intensity of the murmur may change over a number of days. Atrial fibrillation, atrial or ventricular premature depolarizations, and ventricular tachycardia have been observed with bacterial endocarditis.[102,561] One may note swelling of the joints or tendon sheaths.

Laboratory studies obtained from horses with bacterial endocarditis may reveal anemia, hyperproteinemia, elevated fibrinogen, and leukocytosis with a mature neutrophilia.[442] One should perform multiple blood cultures for suspected bacterial endocarditis. The result of blood cultures may be negative, however, particularly after antimicrobial therapy. One is more likely to obtain a positive blood culture by drawing multiple samples at different times of the day during or after febrile episodes. Antibiotic removal system media also might be of value when culturing blood from horses that have received antibiotics recently. 417

Figure 8-40 Bacterial endocarditis: postmortem lesions. **A,** Severe mitral valve endocarditis in a yearling. **B,** Focal aortic valve endocarditis is evident in this view of the left ventricular outlet and the ascending aorta. The septal mitral leaflet is at the lower right, and a jet lesion *(arrow)* is visible in the left ventricular outflow tract. Above the mitral leaflet, in the center of the left coronary cusp, is a raised, irregular vegetation that caused aortic regurgitation. **C,** Tricuspid valve vegetation in a weanling. Although less common than mitral or aortic vegetations, right-sided endocarditis is a definite risk in horses, particularly in animals subjected to repeated jugular venous catheterization. **D,** A lung abscess in a horse following pulmonary valve endocarditis. The center of the abscess is incised and reveals caseous exudate. Systemic embolization and metastatic infection are recognized complications of valvular infections.



One should consider a diagnosis of bacterial endocarditis in any horse that has a fever of unknown origin and the aforementioned clinical signs. Endocarditis is most likely when one cannot isolate the cause of fever to another body system and one suspects concurrent cardiac disease. Positive blood cultures in the setting of compatible

clinical findings or echocardiographic detection of vegetative lesions on the valve leaflets or endocardial surface confirm the diagnosis (Figure 8-42). Vegetative lesions usually appear on echocardiography as thickened, echogenic to hyperechoic masses with irregular or shaggy edges. The valve leaflet usually demonstrates diffuse thickening as well. The typical endocarditis lesion adheres to the endocardium (and therefore moves with the valve). When a fresh thrombus attaches to the vegetation, an oscillatory appearance may be evident with high frame rate, real-time imaging. With time the lesion may contract or develop a smoother contour. Echocardiography also may detect rupture of the chordae tendineae or avulsion of a valve leaflet, and this complication is common in mitral or tricuspid valve endocarditis. One can use pulsed wave and color flow Doppler echocardiography to confirm that the valve is incompetent or (rarely) stenotic. Valvular regurgitation often progresses because of continued damage to the valve leaflets associated with ongoing bacterial infection or following fibrosis associated with a bacteriologic cure.

Treatment of bacterial endocarditis should consist of high levels of bactericidal antibiotics, administered 418
parenterally and ideally based on culture and sensitivity patterns of blood culture isolates. Drugs that penetrate 419
fibrin well, particularly potassium penicillin (22,000 to 44,000 IU/kg every 6 hours), are reasonable initial choices because bacteria may be sequestered in fibrin and may be unavailable to leukocytes. Intravenous therapy is preferable in the initial stages of treatment. To extend the antimicrobial spectrum, one may administer gentamicin sulfate (3.3 mg/kg intravenously every 8 hours). Erythromycin (20 mg/kg every 6 hours intravenously or orally) or rifampin (5 to 10 mg/kg every 12 hours orally) may be useful in some cases. Initial therapy should be broad spectrum until the results of the blood culture are known or when a positive blood culture cannot be obtained. Therapy should extend to at least 4 weeks and as long as 8 weeks. The duration and type of long-term therapy depend on numerous factors, and one must weigh the bacterial isolate, clinical response, cost, and potential toxicosis of the antimicrobial therapy in these decisions.

Figure 8-41 Weight loss, loss of condition, and ventral edema in this weanling with endocarditis and right-sided congestive heart failure (see also Figure 8-40, *C*).

A poor expectation for survival is an appropriate initial prognosis in any case of established bacterial endocarditis. Even in the absence of significant valvular regurgitation, one may have difficulty in achieving a bacteriologic cure, or progressive valvular damage may occur as the vegetation heals and scars the valve. Although some horses have been treated successfully for bacterial endocarditis,[31,160,561] overall the likelihood of long-term survival is low with continued use of the horse as a performance animal or in breeding. The absence of an obvious echocardiographic lesion or signs of systemic inflammatory response creates a more favorable situation, provided that one can obtain a bacteriologic cure. Progressive cardiomegaly, CHF, rupture of the pulmonary artery, atrial fibrillation, or sudden death have been reported in horses affected with endocarditis. Accordingly, one should perform a periodic follow-up examination, including echocardiograms, in successfully treated horses.

Figure 8-42 Two-dimensional echocardiogram of tricuspid valve endocarditis *(arrows),* acquired rupture of the chordae tendineae, and flail tricuspid valve. The movement of the valve from diastole **(A)** to systole **(B)** is evident and is typical of a valvular involvement. The valve is highly echogenic and thick, which is typical of chronic infection. *RA,* Right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

8.8 Pericardial Disease

Pericardial diseases occur uncommonly and usually are associated with pericardial effusion and fibrinous pericarditis.[*] Pericarditis and pericardial effusion may be idiopathic, bacterial, viral, or traumatic or associated with cardiac or pericardial neoplasia. Mesothelioma and lymphosarcoma are the most common neoplasms affecting the pericardium in horses. Pericardial herniae also occur but are rare. Not all cases of pericarditis are septic, but one should consider the possibility of an infectious cause until proved otherwise. Sterile inflammatory and eosinophilic effusates have been recognized, and a recent outbreak of pericarditis centered in Kentucky has been attributed potentially to a caterpillar vector (Figure 8-43). The pathogenesis of noninfective pericarditis is unknown but might be immune mediated in some situations.[91]

419
420

Figure 8-43 Pressure tracing demonstrating elevated right ventricular end-diastolic pressure in a horse with constrictive pericarditis and heart failure. A quick rise occurs from the nadir of pressure *(lower arrow)* to a plateau *(upper arrow),* which is typical of constrictive disease and ventricular filling that is limited to early diastole.

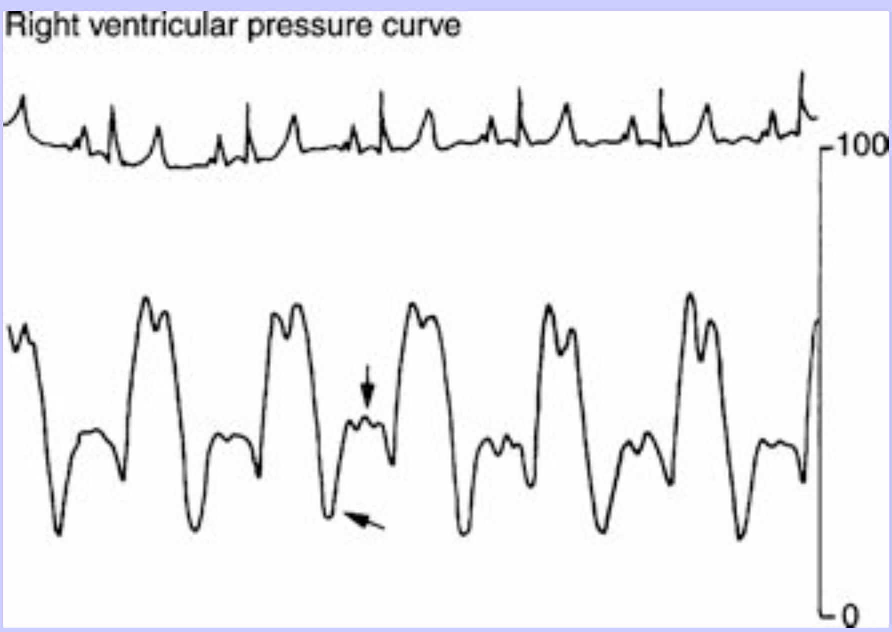

Figure 8-44 **A,** Considerably proliferative epicardial reaction in a horse with idiopathic, fibrinopurulent pericarditis. The heart is covered by a layer of organizing fibrin and inflammatory debris creating a shaggy appearance typical of inflammatory pericarditis. **B,** Two-dimensional long-axis echocardiogram from another horse demonstrating a moderate pericardial effusion. The effusion *(PE)* appears more prominent behind the left ventricle *(LV)* but is also evident *(arrow)* cranial to the right ventricle. *OT,* Left ventricular outflow tract.

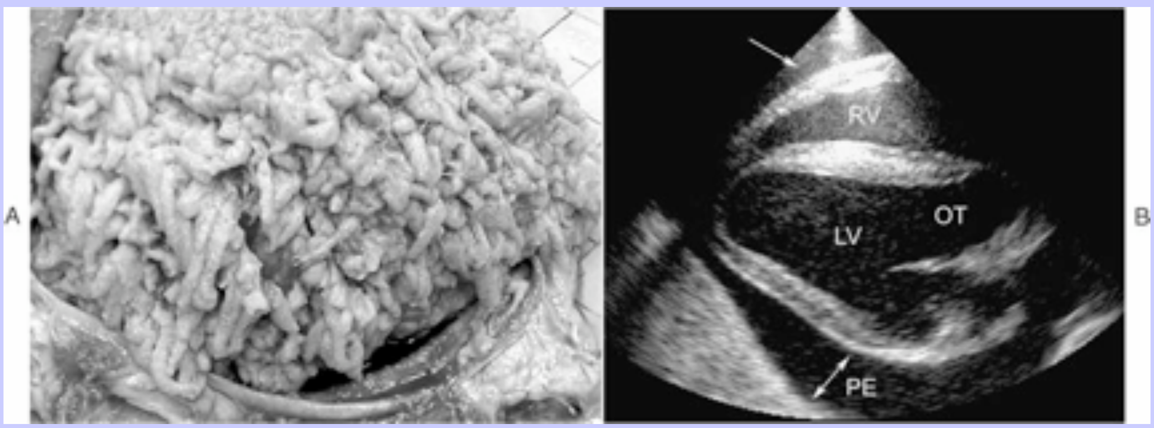

The pathophysiology of pericardial disease in most cases is ascribed to cardiac compression (tamponade) or constriction of the heart with impairment of filling. Occasionally a mass lesion effect compresses the heart, venous drainage, or ventricular outflow. Other clinical signs may be referable to the underlying cause as with infection or neoplasia.

The clinical syndrome of pericardial effusion with tamponade is characterized by impairment of cardiac filling, increases in ventricular filling pressures (Figure 8-44), acutely by reductions in arterial blood pressure, and chronically by normal blood pressure with signs of right-sided CHF. The history usually includes systemic signs of illness such as fever, lethargy, depression, anorexia, tachypnea, ventral edema, colic, and weight loss. External thoracic trauma or penetration by a gastric foreign body may lead to bacterial inoculation of the pericardial space.[566,569,570] A recent history of an upper or lower respiratory tract infection is common. Physical examination abnormalities include various combinations of tachycardia, fever, pericardial friction rub, muffled heart sounds, tachypnea, pleural effusion, jugular and generalized venous distention, ventral edema, thready pulses, and ascites. Arterial blood pressure may be decreased in cardiac tamponade and pulsus paradoxus may be identifiable with careful measurement of arterial blood pressure. In chronic disease, blood pressure is normal because of fluid retention, elevated venous pressures, vasoconstriction, and tachycardia.

Laboratory studies contribute to the diagnosis. Clinical laboratory abnormalities are not specific, but the most 420
frequently detected abnormalities include anemia, hyperproteinemia, hyperfibrinogenemia, and a neutrophilic 421
leukocytosis. Other hematologic abnormalities may be related to inflammation, CHF, or organ hypoperfusion.

Thoracic radiographs usually reveal a globoid cardiac silhouette or pleural effusion and may reveal interstitial pulmonary infiltrates and enlarged pulmonary vessels. The ECG usually demonstrates decreased amplitude of the QRS complexes. If the effusion is large and the heart is swinging, one may observe electrical alternans. Pericarditis may elevate the ST segment in multiple leads, but this change may occur simply as a result of tachycardia. Sinus tachycardia is typical, although one may detect ventricular or atrial premature complexes.

The echocardiographic examination is diagnostic, demonstrating an anechoic or hypoechoic fluid space between the pericardium and epicardial surface of the heart (see Figure 8-44, *B*). Fibrin tags are frequently visible on the parietal and visceral pericardial surfaces. Diastolic collapse of the right ventricle or systolic collapse of the right atrium is diagnostic of cardiac tamponade. Inflammatory processes eventually may lead to adhesion between the parietal and visceral pericardial layers, causing constrictive pericarditis with minimal or no obvious effusion. One can detect associated pleural effusion easily by ultrasound; the finding is common. One also can exclude extracardiac mass lesions, which can mimic pericardial disease, by echocardiography.[94] Echocardiographic diagnosis of constrictive disease without effusion is more challenging, but typically reveals thickened pericardium, atrial dilation, systemic venous dilation, exuberant movement of the ventricular septum, and exaggerated inspiratory filling of the heart as documented by pulsed wave Doppler studies. In some cases, one requires right-sided heart catheterization to establish the diagnosis. Typical findings are increased central venous pressure, elevated RV diastolic pressure, and possibly a diastolic dip and plateau appearance to the RV waveform.[83]

Cytologic evaluation of the pericardial effusion is essential to distinguish septic, aseptic, or neoplastic pericardial effusion. One can obtain fluid in the course of needle pericardiocentesis or during the placement of an indwelling tube for pericardial lavage and drainage. One should perform bacterial culture and sensitivity tests of the aspirated fluid to guide antimicrobial therapy in cases of septic pericarditis. *Streptococcus* spp. have been reported most frequently with pericarditis, but *Actinobacillus equuli, Pseudomonas aeruginosa, Pasteurella* sp., and mycoplasma[572] have been isolated; and equine influenza, viral arteritis, and caterpillar vectors have been associated with fibrinous pericarditis (as well as abortion).

The treatment of pericardial diseases varies, depending on the cause and clinical situation. Pericardiocentesis or catheter drainage is appropriate in all cases of infective pericardial effusion or pericardial effusion with cardiac tamponade. Because the development of cardiac tamponade depends not only on the volume of pericardial fluid but also on the rate at which it accumulates, the clinician's urgency should be guided by blood pressure, clinical signs, magnitude of pleural effusion, and echocardiographic evidence of cardiac tamponade. Tamponade is an indication for immediate drainage of the pericardial sac. One can use echocardiography safely to localize a site for pericardiocentesis and choose an appropriate length of needle, catheter, or drainage tube. One should perform pericardiocentesis after locally anesthetizing the intercostal muscles and pleura and should perform electrocardiographic monitoring continuously during the procedure to monitor for cardiac puncture or in case ventricular arrhythmias develop. One usually performs pericardiocentesis within the left fifth intercostal space, above the level of the lateral thoracic vein, although one can perform the procedure at the right hemithorax. Drainage is achieved using a large-bore catheter, teat cannula, or chest tube; the latter is recommended for repeated drainage and lavage of the pericardial sac and is most successful for aggressive management of septic or idiopathic fibrinous pericarditis. After insertion of an indwelling catheter, pericardial lavage and direct instillation of antimicrobials, combined with systemic antimicrobials, have been shown to be effective in treating septic pericarditis.[510] Pericardial lavage should continue for several days, until accumulation of pericardial fluid declines (<1 L over 12 hours), clinical signs have improved, and the cytologic character of the fluid becomes less inflammatory. If the cytologic analysis and culture are negative for bacteria, one may use antiinflammatory doses of dexamethasone to treat idiopathic, nonseptic, effusive pericarditis.[84,91] Exudative pericarditis may not respond in all cases to conservative treatment or even to drainage. Surgery is a rarely used option for treating pericardial

disease but would be most appropriate for constrictive or constrictive-effusive pericarditis.[83] Presumably, introduction of minimally invasive thoracoscopic surgical techniques to manage pericardial diseases in horses might prove useful.

The prognosis for survival and maintenance of performance in horses affected by pericardial disease is guarded, because the condition may become chronic, but recent reports indicate good results have been obtained.[91] The potential of eventual constrictive or fibrotic pericardial disease is greatest with infective or inflammatory pericardial conditions so that early success may be tempered by later complications of the disease.[84] The best prognosis of horses with fibrinous pericarditis is when treatment includes repeated drainage and lavage. The clinician carefully should follow horses treated by catheter drainage and should reevaluated them by echocardiography. The prognosis for cardiac or pericardial neoplasia is poor.

421

422

8.9 Myocardial Disease

Myocardial diseases are probably underrecognized in clinical practice, and published reports regarding these disorders are few.[*] The potential certainly exists for myocardial injury related to drugs, toxins (ionophore antibiotics, poisonous plants), ischemia, hypoxia, infective agents, parasite migration, heavy metals, trauma, relentless tachyarrhythmia, metabolic disease, or nutritional imbalance. Myocardial injury also can occur from extension of a preexisting infection (pericarditis, pericardial abscess, or endocarditis). Infiltrative cardiomyopathies can occur following neoplasia (melanoma, lipoma, lymphosarcoma, hemangiosarcoma, mesothelioma) or the rare amyloidosis (Figure 8-45; see Table 8-2). Idiopathic, dilated cardiomyopathy also has been recognized in the horse. A potentially reversible cardiomyopathy may accompany relentless ventricular or supraventricular tachycardia. One can assess myocardial function in affected horses only a number of days following conversion to sinus rhythm.

8.9.1 CLINICAL FEATURES

The general manifestations of myocardial disease, regardless of the underlying injury, can be attributed to the following *pathophysiologic processes:*

1. Reduced myocardial contractility and ventricular ejection fraction
2. Diastolic dysfunction with impaired ventricular filling
3. Mitral or tricuspid valve incompetency caused by cardiac dilation or papillary muscle dysfunction
4. The development of arrhythmias

The overall cardiac disability in horses affected by myocardial disease varies greatly. Some horses have no detectable clinical signs, whereas others demonstrate exercise intolerance, life-threatening arrhythmias, low-output CHF, or sudden death.

Persistent ventricular premature depolarizations or ventricular tachycardia are observable in horses with primary myocardial disease. Atrial premature depolarizations, atrial tachycardia, or atrial fibrillation are more often primary electric disturbances, although these arrhythmias also can develop in horses with cardiomyopathies. Although diagnosing myocardial disease in the setting of any cardiac rhythm disturbance is tempting, one should appreciated that many rhythm abnormalities are functional, without a gross anatomic substrate. This point is

especially germane to horses suffering from electrolyte or other metabolic imbalances, high sympathetic tone, sepsis or toxemia, hypoxemia, or ischemia.

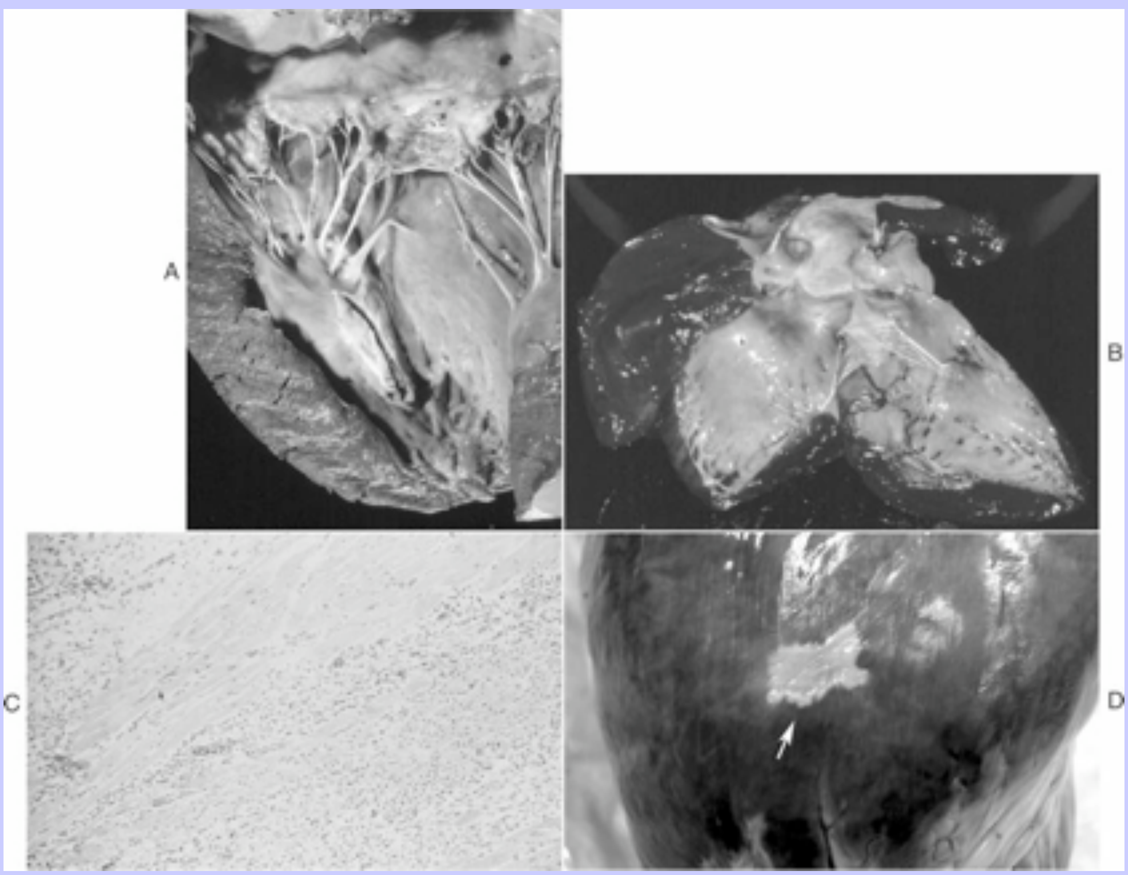
The onset of clinical signs may lag behind the initial myocardial insult, especially in cases of myocarditis or chronic myocardial injury. For example, a horse that apparently has recovered from an illness may develop problems once rigorous training begins. The trainer may complain that the horse is unable to achieve faster speeds or may stop or suddenly slow during hard training. The affected horse may take a long time to cool out after a workout. In more severe cases, significant exercise intolerance, weakness, ataxia, or even collapse may occur. One may detect respiratory distress, pulmonary edema, cyanotic mucous membranes, prolonged capillary refill time, and a rapid, thready pulse after exercise. In case of severe myocardial injury, one may observe signs such as fever, persistent tachycardia, arrhythmia, murmur, pulmonary or ventral edema, or respiratory distress. Sudden death may occur without premonitory signs.

Results of the *clinical examination* in horses with myocardial disease are inconsistent. Resting physical examination findings can be normal, or signs of heart disease may be evident. These can include persistent tachycardia, tachypnea, frequent premature beats, sustained arrhythmias, systolic murmurs of atrioventricular valvular insufficiency, or CHF. A postexercise examination often detects an abnormally rapid heart rate, which remains persistently high after exercise is discontinued. The ECG may demonstrate atrial or ventricular arrhythmias, and an exercise ECG typically records an inappropriately high heart rate for the level of work undertaken. Resting echocardiography usually reveals a low normal or unambiguously reduced ventricular shortening fraction. Postexercise echocardiography may demonstrate a paradoxical reduction of LV shortening fraction or regional dysfunction characterized by LV wall motion abnormalities. One may observe significant increases in LV or LA spontaneous contrast with poor myocardial function, although this is not a specific finding (Figure 8-46). Abnormal areas of myocardial echogenicity have been observed, but myocardial tissue characterization by echocardiography is not well established in horses and depends on technical factors.

Clinical laboratory tests may be useful for identifying myocardial damage but may not necessarily distinguish myocarditis from myocardial cell injury induced by a toxin or by ischemia. Elevated plasma or serum myocardial fractions of creatine kinase or of lactate dehydrogenase suggest myocardial injury.[272] A more specific marker of myocardial is elevation of serum troponin I.[584,585] Although normal values or mild elevations do not exclude cardiomyopathy or myocardial infiltration, elevated values point to cardiac muscle damage.

Diagnosis of myocardial disease requires clinical suspicion and integration of findings from clinical and laboratory examinations. Because of the extreme variability of findings, one can make the presumptive diagnosis of myocardial disease only after reviewing the history, physical examination, echocardiogram, ECG, and clinical laboratory tests. Definitive diagnosis of myocarditis requires transvenous endomyocardial biopsy, but this test is impractical and may not identify piecemeal inflammation, degeneration, infiltration, or necrosis. 422 423

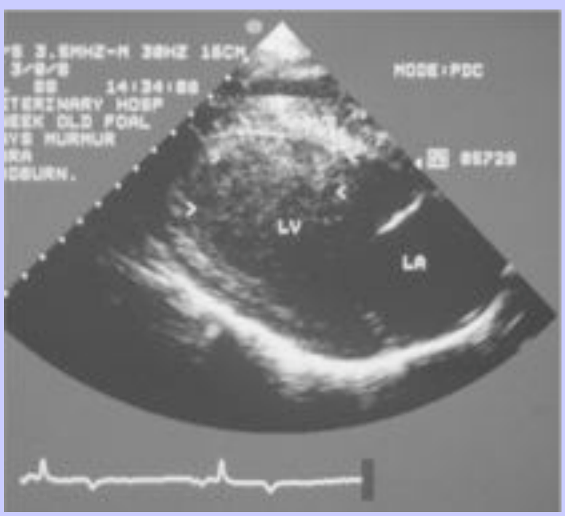
Figure 8-45 Myocardial diseases. **A,** An opened left ventricle revealing an *(incised)* large, oval area of subendocardial and myocardial fibrosis in a mare. No causative agent was found. **B,** Significant left ventricular dilation and subendocardial fibrosis in a horse with idiopathic dilated cardiomyopathy. The white discoloration of the left ventricle and left atrium may result from chronic distention or represent fibrosis following another injury. The opened right ventricle *(to the left)* is dilated but is not discolored. **C,** Myocardial lymphosarcoma. A substantial myocardial infiltration is evident in this photomicrograph. **D,** Close up of a left ventricular, subepicardial myocardial infarct *(arrow)* of undetermined cause.



Treatment of horses affected by myocardial disease is primarily supportive. Prognosis depends on the cause and severity of myocardial injury and the hemodynamic consequences of myocardial disease. All horses should be rested, preferably in a stall, until myocardial function, ECG, cardiac isoenzymes, and serum troponin return to

normal or at least remain stable for several weeks. The horse should rest a minimum of 1 month (and usually more) before returning to work. The clinician administers antiarrhythmic therapy when indicated for potentially life-threatening arrhythmias (see the following discussion in this chapter). Treatment of frequent premature supraventricular or ventricular complexes with an antiarrhythmic agent can be effective; however, the arrhythmia may return as soon as the antiarrhythmic drug is discontinued. If practical, the administration of an ACE 423
inhibitor such as enalapril or ramipril is recommended to reduce myocardial remodeling and unload the ventricle. 424
When CHF has developed, digoxin and furosemide are prescribed as described in the section on CHF. One should undertake digitalization with caution in horses with ventricular extrasystoles, because treatment may aggravate the arrhythmia. Digoxin is not indicated in monensin toxicosis (see the following discussion). If one believes noninfective myocarditis to be the cause of the arrhythmia or clinical signs, corticosteroid therapy may be indicated, although its value is unsubstantiated. When the principal manifestation of myocardial disease is electric (arrhythmias with otherwise normal myocardial function), the prognosis is fair to good for resolution of the arrhythmias. Horses with decreased myocardial function by echocardiography or those with CHF must be given a guarded prognosis for life and a poor prognosis for future performance. One should note, however, that some horses with acute onset of CHF have recovered completely and returned to their prior performance level. Such horses most likely suffered from acute myocarditis that resolved spontaneously or following antiinflammatory therapy. Other horses may achieve a less spectacular recovery but still serve successfully as breeding animals.

Figure 8-46 Spontaneous contrast in the apex of the left ventricle of a foal. The echodensities swirled in real time. One can compare the left ventricular density with the density within the left atrium. Bradycardia, low cardiac output, and rouleaux formation are thought to contribute to this finding (see also Figure 8-38, *A*).



* References 3, 28, 29, 72, 92, 99–100, 103, 106, 107, 112, 114, 527, 573–583.

8.9.2 MYOCARDITIS

Myocardial inflammation, or myocarditis, is difficult to diagnose. The diagnosis often is entertained in horses with cardiac arrhythmias or abnormal myocardial function, particularly when cardiac signs occur after another illness and are associated with elevated cardiac isoenzymes and serum troponin I concentrations. Often the prior disorder is a viral, influenza-type condition or an infection caused by *Streptococcus* spp. The logical conclusion is that immune-mediated myocarditis is operative in these cases, but definitive cause-and-effect proof is lacking because of the difficulty of obtaining myocardial biopsies. Myocarditis also may follow parasitic migration, pericarditis, or bacterial endocarditis. Hematogenous spread to the heart may be another mechanism for myocarditis. Severe necrotizing myocarditis can lead to arrhythmias or to signs of myocardial dysfunction as discussed previously. The signs, prognosis, and treatment of myocarditis are similar to that described in the preceding section.

8.9.3 TOXIC INJURY OF THE MYOCARDIUM

A number of chemicals and plant toxins are potentially injurious to the myocardium. Ionophore antibiotics are among the most notorious causes of myocardial necrosis in horses.[106–111] Toxic myocardial injury also can occur following ingestion of glycoside-containing Japanese yew plants or cut oleander,[586] or from eating feed contaminated by *Epicauta* species (blister beetles) that contain the toxic element cantharidin.[576,578,587] Myocardial necrosis also occurs following endotoxemia, particularly with clostridial infection, salmonellosis, and torsion of the large colon. Rattlesnake venom has been associated with cardiac injury and arrhythmias.[588]

Horses are uniquely sensitive to ionophore antibiotics, which are used as a coccidiostat in poultry production and as a growth promoter in steers. Monensin toxicosis (>2 to 3 mg/kg) has occurred most frequently, but salinomycin (0.6 mg/kg or higher) and lasalocid (21.5 mg/kg or higher) also have caused myocardial injury and death in horses. Ionophores react with polar cations to form lipid-soluble complexes, leading to cation transport across myocardial cell membranes. Various ionophores demonstrate particular affinities for different cations, though lasalocid may complex with a variety of ions. Exposure of horses to the ionophore antibiotics usually stems from accidental contamination of equine feedstuffs at the mill or through accidental delivery of poultry or cattle feeds to horses. In most outbreaks the culprit was a recently acquired ration.

Clinical signs of horses with ionophore toxicity vary with the specific type, quantity, and concentration of ionophore ingested and the preexisting health and body condition of the exposed horses. A wide range of clinical signs has been observed by one of the authors (Reef) in exposed horses ranging from none to clinical signs involving almost all body systems. Weakness, lethargy, depression, anorexia, ataxia, colic, diarrhea, profuse sweating, and recumbency have been observed. The cardiac findings are similar to those previously described for 424
myocardial diseases. If sudden death occurs, it is usually within 12 to 36 hours of ingestion of the contaminated 425
feed. Polyuria and hematuria also have been reported in ponies. A diagnosis of ionophore toxicity is based on the detection of the ionophore in the feed or stomach contents of exposed horses. One may observe various clinicopathologic abnormalities with monensin toxicity, including decreased serum calcium, potassium, magnesium, and phosphorus; and increases in serum urea, creatinine, unconjugated bilirubin, aspartate aminotransferase, creatine phosphokinase, and lactate dehydrogenase. Isoenzyme patterns of creatine phosphokinase and lactate dehydrogenase have indicated cardiac, skeletal, and red blood cell damage. Elevated packed cell volume and total solids have been associated with dehydration. Echocardiographic evaluation of affected horses has revealed significant decreases in shortening fraction with segmental wall motion abnormalities that range from mild to severe. Horses that exhibit decreased shortening fraction and dyskinesis

shortly after exposure to monensin generally do not survive. Horses with mild decreases in shortening fraction survive and may be useful breeding animals, but most do not return to previous performance levels. Horses with normal echocardiograms not only survive but also typically return to work at their previous level. Postmortem findings range from no visible lesions in horses with normal echocardiograms to severe myocardial necrosis and fibrosis in those with decreased shortening fraction or ventricular dyskinesis. A single dose may lead to death from cardiac arrhythmias before the development of myocardial necrosis. Postmortem lesions have been described elsewhere but include myocardial pallor and signs of CHF.

Treatment for affected horses is largely symptomatic (see the previous discussion), unless recent exposure is known. Vitamin E has been suggested to have a protective effect in other species and may be beneficial in affected horses. Digoxin and probably calcium channel blockers are contraindicated in acutely affected horses. If ingestion of the contaminated feedstuff is recent, treatment with activated charcoal or mineral oil is indicated to reduce absorption of the ionophore. Intravenous fluid and electrolyte replacement therapy may be indicated, as well as antiarrhythmic drugs, for any life-threatening arrhythmias. Stall rest in a quiet environment for up to 8 weeks after exposure is most important, because echocardiograms recorded after trivial exercise or excitement can reveal residual disease characterized by significant decreases in fractional shortening and myocardial dyskinesis.

8.9.4 DILATED CARDIOMYOPATHY

Idiopathic dilated cardiomyopathy is a disorder of the myocardium characterized by global reduction of LV systolic function that cannot be explained by valvular, vascular, coronary, or congenital heart disease. The inciting cause of dilated cardiomyopathy generally is undetermined, although myocarditis or prior toxic injury often is suspected. Relentless junctional or ventricular tachycardia also can lead to a dilated cardiomyopathic state. The clinical signs are similar to those described for myocardial diseases. Echocardiography is diagnostic, revealing cardiomegaly with biatrial and biventricular dilation and depressed shortening fraction (see Figure 8-20, *A*). Symptomatic therapy with digoxin and diuretics may stabilize CHF temporarily and lead to transient improvement, but most horses deteriorate in the 3 to 12 months after diagnosis and are destroyed humanely. Neither the history nor the postmortem examination reveals the cause, and generally only diffuse or multifocal myocardial degeneration, necrosis, and fibrosis are observed.

A form of dilated cardiomyopathy also can be caused by vitamin E and selenium deficiency and occurs primarily in fast-growing foals from mares with a marginal or deficient selenium status raised in selenium-deficient areas. Affected foals are usually younger than 6 months of age and have an acute onset of weakness, recumbency, respiratory distress, pulmonary edema, tachycardia, murmurs, and arrhythmias. The prognosis for foals affected with the myocardial manifestations of white muscle disease are poor, and most die within 24 to 48 hours after the onset of clinical signs. Laboratory abnormalities in affected foals include significant elevations of creatine kinase (including the cardiac isoenzyme or MB fraction in foals with myocardial involvement), aspartate aminotransferase, and lactate dehydrogenase, as well as hyperkalemia, hyponatremia, and hypochloremia. Myoglobinuria may occur. Echocardiography demonstrates the severity of myocardial involvement. Whole blood selenium, red blood cell glutathione peroxidase, and vitamin E levels may be helpful in the diagnosis; however, tissue samples provide a more accurate indication of selenium stores. Treatment with vitamin E and selenium might be successful, but typically the myocardial necrosis is extensive and incompatible with life. Postmortem findings reveal pale streaking of the myocardium with intramuscular edema, myodegeneration, myocardial necrosis, and fibrosis or calcification. Prevention of white muscle disease is important in selenium-deficient areas. Supplementation of pregnant mares should occur during gestation based on individual blood and tissue selenium levels and should continue during lactation, because more selenium is passed to the foal through the milk than across the placenta.

8.10 Vascular Diseases

Diseases of the arteries and veins can be congenital or acquired. Acquired disorders include a variety of conditions, varying in cause and ranging from subclinical to devastating.[*] Thrombophlebitis is probably the most common vascular problem encountered in clinical practice. Catheter embolization occurs periodically and has been amenable to surgical and percutaneous catheter retrieval.[610,611] Venous aneurysms,[591] vascular and lymphatic malformations, and angiomatous lesions are rare.[535] Lesions related to arteriosclerosis and arterial thrombosis are thought to be caused by parasite migration in the gastrointestinal (particularly the mesenteric) arteries[612] and at the terminal aortic quadrifurcation. Rupture of the aorta is usually a life-threatening event or leads to severe sequelae. Rupture of an aortic sinus aneurysm into the ventricular septum or right-side heart chambers; aortic rupture into the pericardium in older breeding stallions; and acquired aortic-pulmonary fistula have been reported.[34,57,196,434,609] Aortic inflammation of unknown cause has been observed.[436,444] Rupture of the pulmonary artery is a potential result of long-standing pulmonary hypertension and left heart failure. Arteriovenous communications occur rarely and may develop after vascular rupture or following growth of vascular tumors. Pulmonary vascular disease and associated hypertension may place a load on the right ventricle, a condition called cor pulmonale. However, no compelling evidence at this time incriminates cor pulmonale as an important or common cause of heart disease in horses. Idiopathic pulmonary hypertension has been reported as a cause of atrial fibrillation in horses; however, left-side heart dysfunction was not excluded completely in the reported cases.[61] Tumors of the great arteries and veins are rare.[535] Mycotic disease within the guttural pouch is a well recognized cause of arteritis and rupture of the internal carotid artery (see Chapter 7). 425 426

The echocardiographic observation of intravascular, spontaneous contrast within blood vessels and cardiac chambers has been suggested to indicate cardiovascular or rheologic disease.[413,613] This observation is common during ultrasound examinations and contrast may be observed in a variety of vessels and in the heart. Pronounced spontaneous echo contrast is especially likely when low flow rates are caused by bradycardia, arrhythmia, or myocardial failure or when actual obstruction to blood flow in vessels occurs. Contrast is often prominent in valvular endocarditis. Lesions, thrombosis, or even venipuncture of the jugular vein can lead to spontaneous echo contrast in systemic veins and the right side of the heart, becoming more obvious if CO suddenly increases. The identification of spontaneous contrast also depends on the operator with respect to transducer, gain, and gray-scale contrast settings (see Figure 8-46). The clinical significance of isolated intravascular contrast cannot be stated with certainty. Prominent contrast is observable with some cardiovascular diseases and has been suggested to indicate abnormal platelet function. However, in the majority of horses, spontaneous contrast probably represents a normal phenomenon. Currently, no compelling evidence indicates that, in the absence of other vascular or cardiac lesions, appearance of spontaneous contrast is abnormal.

One often can suspect serious vascular disease from the clinical examination, although it may not be obvious until a catastrophic vessel rupture or fatal hemorrhage occur. In general, significant *arterial* disease reduces perfusion to the affected vascular bed, impairing tissue metabolism and function. If severe or complete, ischemia may lead to tissue necrosis (infarction) and even perforation of a hollow organ. A bruit—auscultatory evidence of vascular narrowing or rupture—may occur over the affected artery, or hemorrhage may be obvious if a superficial vessel has ruptured. Ultrasound and Doppler examinations can demonstrate serious arterial disease, provided an acoustic window for examination exists. Angiography or nuclear scintigraphy rarely is required to demonstrate arterial thrombosis or disruption. In major venous disease, the typical sign is swelling of soft tissues drained by the affected vessel. Palpable evidence of local inflammation and thrombosis may be found in superficial venous disease. Right-

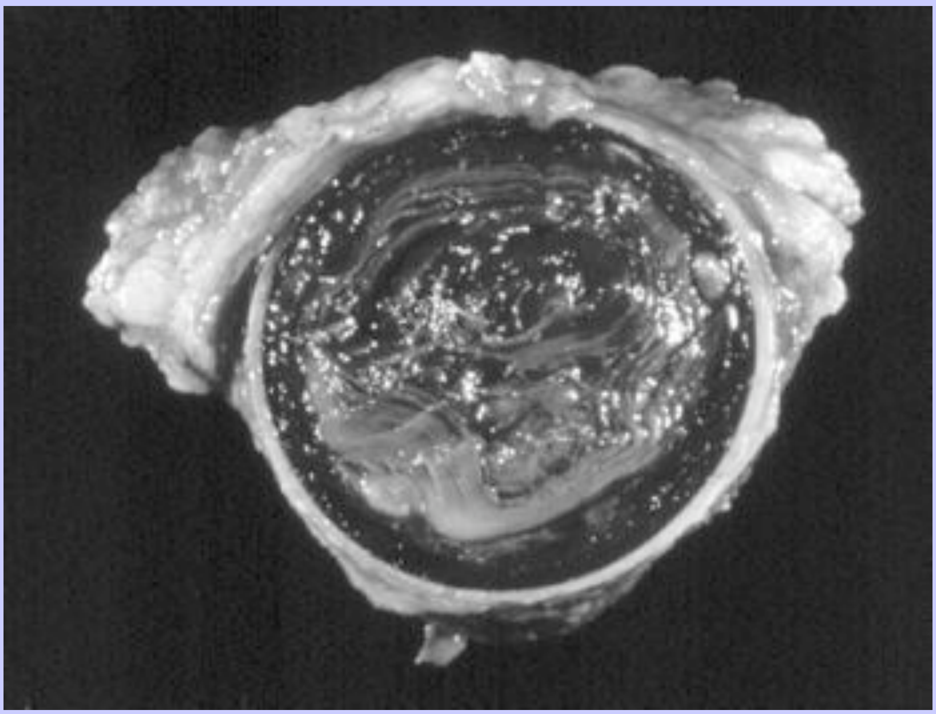
sided endocarditis, embolic pneumonia, and pulmonary embolism are potential consequences of systemic venous disease.

8.10.1

THROMBOPHLEBITIS

Intravenous catheterization or intravenous injection most commonly causes thrombophlebitis, the inflammation 426
and thrombosis of a vein (Figure 8-47),[349,600] which most often affects the jugular veins. Thrombophlebitis can 427
develop in the absence of preexisting vessel trauma following coagulation disorders. Clinical signs of phlebitis are straightforward, including swelling over the affected vein, and pain on palpation of the involved tissues. Thrombotic occlusion results in distention of the veins and possibly subcutaneous edema proximal or cephalad to the affected area. Significant swelling, heat, and pain on palpation, combined with fever, hyperfibrinogenemia, or a neutrophilic leukocytosis, indicate infection of the thrombus.

Figure 8-47 Thrombosis of a jugular vein following iatrogenic thrombophlebitis.



The diagnosis and assessment of thrombophlebitis is based on the detection of the previously described clinical signs and examination by duplex Doppler ultrasonography. Imaging of the affected vein reveals filling of the lumen with an anechoic, hypoechoic, hyperechoic (if gas filled), or mixed echogenic material that partially or completely occludes the vessel (Figure 8-48). Ultrasonographic evaluation also may reveal thickening of the vessel wall, perivascular swelling, tracts extending from the vein to the subcutaneous tissues or skin, or subcutaneous abscesses. Cavitation in the center of a thrombus suggests infection and represents a target for aspiration and bacterial culture. Stagnant or turbulent flow may be manifested by increased spontaneous venous contrast. One may evaluate the flow across the affected zone by pulsed wave or color-coded Doppler studies or with contrast venography using agitated saline as a contrast agent. One also should assess venous drainage

proximal and distal to the area of thrombosis because collateral circulation still may enter the vein distally. One should perform a careful evaluation of the communicating large veins and of the heart in horses with infective thrombophlebitis. Bacterial endocarditis may develop following embolization of infective thrombus or bacteremia.

Figure 8-48 Vascular imaging: jugular veins. **A,** Ultrasound image of normal jugular veins. The echolucent lumina of the right and left veins are indicated. The image is just off transverse. **B,** Image of a mixed, echogenic thrombus *(arrows)* in the right jugular vein. Doppler studies could be used to evaluate the flow across this area.

The clinician should anticipate infections in multiple organisms in cases of infective thrombophlebitis and should administer high doses of broad-spectrum antimicrobials until culture and sensitivity results of the aspirate are available. One should consider metronidazole (15 mg/kg every 6 hours) if one suspects anaerobic infection and may add flunixin meglumine (1 mg/kg every 12 hours) to reduce inflammation. Local therapy including hot compresses, topical ichthammol, or dimethyl sulfoxide may be helpful in treating thrombophlebitis. If antimicrobial therapy is unsuccessful, surgical resection of the affected vein may be indicated. Recanalization of an affected vein often occurs and can be documented by Doppler or contrast ultrasound studies demonstrating blood flow between the vessel wall and the thrombus. Occasionally, one may detect loculation within the ends of the thrombus. Such loculation may result in persistent fibrous webs within the vein that restrict venous return. Venous stricture also may occur following long-standing thrombophlebitis. Complete fibrous occlusion of the jugular vein (see Figure 8-47) may impede venous return from the head such that if adequate collateral circulation does not develop, impaired venous drainage of the head and neck may limit performance.

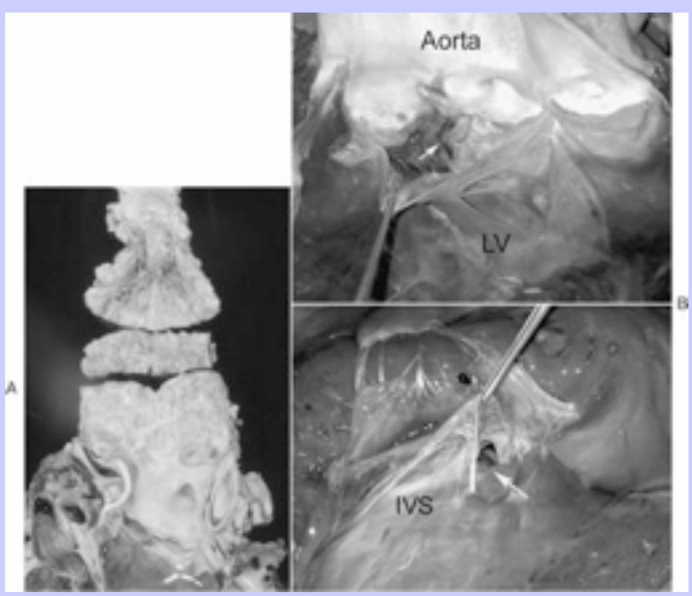
8.10.2 AORTIC-ILIAC THROMBOSIS

Aortic-iliac thrombosis is an uncommon but potentially serious disorder. The gross appearance, histologic features, and clinical findings of this vasoocclusive disorder have been reviewed extensively, and the interested reader is directed to these and other related reports.[*] Arteriosclerotic and atherosclerotic aortic lesions also have been observed at other sites as well (see Figure 8-49). Suggested causes of arterial disorders such as these include *Strongylus vulgaris* infection, systemic infections, embolization, and vasculitis. No convincing evidence indicates that *Strongylus* infection consistently causes aortic-iliac thrombosis, and Azzie[199,201] has refuted this contention. The terminal aorta and the iliac arteries, including their proximal branches, are the focus of 427
428 involvement. Vessels become partially to completely occluded by multifocal ingrowths of fibrous tissue, laminated thrombi, or fibrous plaques.[197] Histologic lesions include organized, fibrous connective tissue, hemosiderin-laden macrophages, irregular vascular channels, and disruption of the intima and internal elastic lamina. The lesions are generally devoid of fat.

Figure 8-49 Aortic disease. **A,** Severe atheromatous change with secondary *Streptococcus* infection of the proximal aorta. The intimal and subintimal change begins just distal to the coronary ostia. Representative sections of the ascending aorta are shown. *Strongylus vulgaris* was not found. The most distal segment was necrotic and severely narrowed flow across the region. **B,** Dissecting lesion communicating the root of the aorta *(top panel, arrow)* to the right side of the heart across the intraventricular septum *(IVS)*. The distorted tricuspid valve is retracted to demonstrate the lesion on the right *(arrow)*.



Although aortic-iliac thrombosis is uncommon, it can be associated with severe performance problems, including reproductive failure.[601] The typical features include exercise-associated, typically unilateral hindlimb lameness, ataxia, or collapse.[197,199,201,202] Aortic-iliac thrombosis also has been diagnosed as a cause of breeding failure in stallions.[199,201,202] Physical examination of an affected horse at rest may reveal weak metatarsal arterial pulses or delayed saphenous refill in the affected limb. The temperature of the limb in the resting animal is usually normal, unless complete arterial occlusion has occurred, in which case the limb is cold and painful and may become edematous. Exercise in affected animals results in an exercise-associated gait abnormality (lameness, ataxia, or weakness) with a decreased or absent metatarsal and digital pulse and delayed or absent saphenous refill. Claudication may cause the horse to become uncomfortable and reluctant to bear weight on the affected limb. Significant hyperpnea, other signs of distress, and profuse, generalized sweating are often present with trembling of the affected limb. A rectal examination may reveal fremitus, a weak or absent pulse, or aneurysmal dilation of the affected artery or arteries. These abnormalities may be more evident after exercise and may help to confirm the diagnosis. 428

429
Ultrasonographic evaluation of the terminal aorta and iliac arteries (Figure 8-50) with a high-frequency (5- or 10-MHz) rectal transducer[198,200,348] or nuclear techniques[616] can confirm diagnosis. Doppler studies may indicate abnormal blood flow in the femoral arteries.[617] Essential abnormalities include a hypoechoic to echogenic mass protruding into the arterial lumen. One can estimate the degree of obstruction based on the percentage of the artery occluded. Many cases are long-standing, and hyperechoic areas, even tissues sufficiently echodense to cast acoustic shadows, may be imaged within the aortic or iliac thrombus. These findings suggest mature scar tissue and calcification.

The prognosis for this disorder is guarded. No controlled studies have evaluated therapy for this condition, though prior experience, including a recent case survey,[618] suggests no treatment consistently improves outcome. In cases of acute thrombosis associated with degenerative or inflammatory disease, surgical or catheter-based thrombectomy has potential benefit. Various medical treatments have been reported, including intravenously administered sodium gluconate, larvicidal dewormings, phenylbutazone, low-molecular-weight dextran, and a controlled exercise program. Early diagnosis is essential if therapy is to be beneficial. Treatment aims at improving collateral circulation and preventing additional thrombus formation.

* References 118, 197–202, 347, 348, 594, 601, 614–616.

8.10.3 PARASITIC INFECTION

The migrating larval forms, particularly L_4 of *S. vulgaris,* are known causes of arterial disease, particularly involving the aorta and the cranial mesenteric artery and its branches (Figure 8-51). Lesions have been described as far forward as the bulbous aorta and the aortic sinuses in infected horses. Rounded fibrous plaques and mural thrombi have been reported in the thoracic and cranial abdominal aorta in 9.4% of horses examined immediately after death by Cranley and McCullagh.[99] These investigators reported a statistical association between the occurrence of proximal aortic *S. vulgaris* lesions and the presence of focal ischemic lesions in the myocardium. They hypothesized that these lesions resulted from microembolism from parasitic lesions. With the advent of ivermectin and other new anthelmintics, and aggressive deworming programs currently recommended by practicing veterinarians, heavy *S. vulgaris* larval migration damage occurs less frequently. However, one must consider migration of *S. vulgaris* L_4 larvae in horses with poor deworming histories, high potential of exposure, high fecal egg counts, and palpable abnormalities on rectal examination or on finding fremitus or aneurysmal dilation of the aorta, particularly in the region of the cranial mesenteric artery or iliac system. An

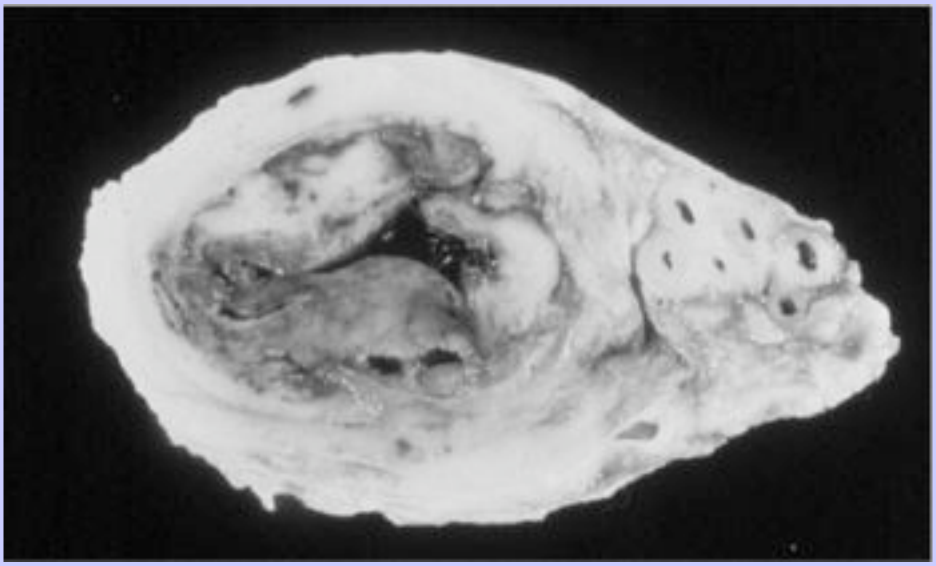
ultrasonographic evaluation of the cranial mesenteric artery is possible and can be used to confirm the diagnosis of thrombosis in these vessels (see Figure 8-51).[598,618] Treatment should consist of larvicidal deworming, combined with a rigorous individual and environmental parasite control program.

Figure 8-50 An ultrasound image of a distal aortic thrombosis obtained by transrectal probe. The thrombus, with hyperechoic areas and probable calcification as well as patent areas of the lumen with enhanced intravascular contrast effect, is evident.

8.10.4 ARTERIOVENOUS FISTULAE

Arteriovenous fistulae occur uncommonly and most often are detected with large vascular tumors (hemangiomata, hemangiosarcomata) or as a rare congenital defect or posttraumatic sequela.[597] Classic features include a continuous thrill and murmur over the affected area, localized edema, slowing of the heart rate after occlusion of the shunt, and signs of increased CO if the shunt flow is great. One can make a diagnosis with Doppler ultrasound, including pulsed wave and color flow Doppler to demonstrate continuous and pulsatile flow from the artery through the associated communication into the distended veins. The clinician should perform a 429
complete cardiovascular examination because a large arteriovenous communication could lead to cardiac failure. 430
Treatment depends on the underlying cause. No treatment may be indicated with small, uncomplicated arteriovenous communications. Large vascular neoplasms are usually inoperable at the time when they are diagnosed or are complicated by the possibility of metastasis.

Figure 8-51 Verminous arteritis and thrombosis in the cranial mesenteric artery caused by *Strongylus vulgaris*.



8.10.5

ARTERIAL RUPTURE

Rupture of the aorta or its branches or of the pulmonary artery are reported sporadically. Rupture of the aortic root has been reported commonly in older horses, usually older breeding stallions, but also may occur in older mares or in younger horses.[57] Rupture typically involves the right aortic sinus (of Valsalva). The aortic root can rupture into the right atrium, right ventricle, intraventricular septum, or pericardial space.[57,142,434,441] Dystrophic changes in the media of the aorta have been reported, and the hypertension associated with breeding has been implicated as a cause of aortic root rupture. Aneurysms of the right sinus of Valsalva also have been reported and are related to congenital defects in the media of the aorta near the right coronary sinus. Rupture of the middle uterine artery can lead to fatal peripartum hemorrhage.[195] Ruptures of the extrapericardial aorta or other blood vessels leading to fatal hemorrhage or a systemic to pulmonary shunt have been reported.[52,56–59,61,63–67]

Rupture of an artery is often a catastrophic event, and most diagnoses are made at the necropsy floor. Antemortem diagnosis of an aortic sinus of Valsalva aneurysm is possible by echocardiography. Aside from breeding, owners should not use horses with diagnosed aortic aneurysms or arterial-cardiac fistulae for athletic endeavor, because rupture of the aneurysm could occur at any time. When aortic root rupture or rupture of a sinus of Valsalva aneurysm communicates with the right atrium or right ventricle, right-sided heart failure can occur. The aortic-cardiac fistula causes a continuous heart murmur. Cardiac arrhythmias (usually ventricular tachycardia) also may develop, especially if dissection progresses into the intraventricular septum.[441] The prognosis for life in these horses is generally grave depending on the site and size of the communication. Some horses survive with supportive treatment for CHF.

Chronic pulmonary hypertension and pulmonary artery dilation most often cause pulmonary artery rupture. One detects rupture most commonly along with severe chronic MR, but rupture may occur in any horse with severe

pulmonary hypertension, regardless of the cause. One should consider the potential for pulmonary artery rupture whenever echocardiography detects a large, dilated main pulmonary artery or left and right pulmonary artery. Owners should consider affected horses unsafe for riding or driving and should not use them, except for breeding, because of the possibility of sudden death (see Figures 8-39 and 8-49). Focal medial calcification of the pulmonary artery is a common finding at necropsy.[432]

8.11 Cardiac Arrhythmias

Cardiac arrhythmias are disturbances in heart rate, rhythm, or conduction and can be classified based on atrial and ventricular rate, anatomic origin of the impulse, method of impulse formation, and conduction sequence. A variety of cardiac arrhythmias have been recognized.[493,619] Of principal concern to the clinician are the hemodynamic consequences of arrhythmias (reduced pressure, flow, and perfusion) and the potential for further electric instability (myocardial fibrillation, sudden death).

The electrophysiologic basis of cardiac arrhythmias will not be discussed, and the interested reader is referred elsewhere for descriptions of abnormal automaticity, reentry, reflection, entrainment, and other cellular mechanisms of arrhythmogenesis. Cardiac arrhythmias are classified based on the anatomic origin of the manifest ECG mechanism (Box 8-9). The reader should be aware that some arrhythmias, especially those originating in the atrioventricular junction, may mimic atrial rhythm disturbances or high ventricular rhythms. For the purpose of discussion, the authors have elected to distinguish *atrial* from *junctional;* however, one also may apply the term *supraventricular* to these rhythm disturbances. Box 8-10 reviews the clinical evaluation of the horse with an arrhythmia.

8.11.1 SINUS RHYTHMS

A number of physiologic sinus rhythms are recognized and can be explained by the effect of autonomic nervous system traffic on the sinoatrial node (Figure 8-52). Normal horses at rest demonstrate vagal-mediated sinus bradycardia, sinus arrhythmia, or sinus block or arrest; yet fear or a sudden stimulus may provoke sympathetically driven sinus tachycardia. Exercise leads to pronounced sinus tachycardia with heart rates often exceeding 200 beats/min. As a general rule, atrioventricular conduction tends to follow sinus activity. During sinus tachycardia, the P-R interval shortens, whereas during periods of progressive sinoatrial slowing, the P-R interval prolongs. Usually second-degree atrioventricular block, type I (Wenckebach), follows a progressive prolongation of the P-R interval. Sinus rate and atrioventricular conduction usually change in parallel; however, some horses appear to control blood pressure during high sinus tachycardia by blocking impulses in the atrioventricular node. Second-degree atrioventricular block is more likely in a standing horse, in a horse that suddenly has stopped submaximal exercise, or after a brief surge of sinus tachycardia in an anxious animal. 430 431

8.11.1.1 BOX 8-9 CARDIAC RHYTHMS OF THE HORSE

8.11.1.1.1 Sinus Mechanisms*

Normal sinus rhythm

Sinus arrhythmia

Sinoatrial block or arrest

Sinus bradycardia

Sinus tachycardia

8.11.1.1.2
Atrial Rhythm Disturbances

Atrial escape complexes[†]

Atrial premature complexes

Atrial tachycardia: nonsustained and sustained

Atrial flutter

Atrial fibrillation

Reentrant supraventricular tachycardia

8.11.1.1.3
Junctional Rhythm Disturbances

Junctional escape complexes[†]

Junctional escape rhythm[†] (idionodal rhythm)

Junctional premature complexes

Junctional (“nodal”) tachycardia

Reentrant supraventricular tachycardia

8.11.1.1.4
Ventricular Rhythm Disturbances

Ventricular escape complexes[†]

Ventricular escape rhythm[†] (idioventricular rhythm)

Ventricular premature complexes

Accelerated ventricular rhythm (idioventricular tachy-cardia)

Ventricular tachycardia

Ventricular flutter

Ventricular fibrillation

8.11.1.1.5
Conduction Disturbances

Sinoatrial block[*]

Atrial standstill (hyperkalemia)

Atrioventricular blocks: first degree,* second degree,* third degree (complete)

Ventricular preexcitation

* Generally physiologic.

† Escape complexes develop following another rhythm disturbance.

One must monitor sinus rate and rhythm carefully in the critically ill or anesthetized horse because heart rate is a major determinant of CO and arterial blood pressure. Sedative drugs and anesthetics can cause sinus bradycardia. Anesthetic drugs or hypoxia can depress sinus node function, as can traction on an abdominal viscus. Concurrent depression of the sinus node with stimulation of latent pacemakers in the coronary sinus or atrioventricular junction can lead to ectopic rhythms in the anesthetized horse. Conversely, an increasing sinus rate may indicate 431
inadequate depth of anesthesia, pain, or hypotension. On identifying sinus tachycardia, one must seek out and 432
treat the cause. One should consider and manage the possibilities of pain, hypotension, and sepsis when appropriate.

8.11.1.2

BOX 8-10 EVALUATION OF THE HORSE WITH

General medical history, past illnesses, past and current medications

Work history and exercise tolerance

General physical examination

Physical examination: evidence of congestive heart failure

- Subcutaneous edema
- Jugular venous distention and pulsations
- Pulmonary edema
- Pleural and peritoneal effusion
- Weight loss, poor condition

Auscultation of the heart

- Assessment of heart sounds (rhythm, third heart sound)
- Assessment of heart murmurs

Resting electrocardiogram

- Heart rate and cardiac rhythm
- Analysis of P-QRS-T waveforms

Postexercise electrocardiogram

Exercise (or treadmill) electrocardiogram

Clinical laboratory studies

- Complete blood count (rule out anemia, infection)
- Blood culture (in cases of suspected endocarditis)
- Serum electrolytes (particularly potassium and possibly magnesium)
- Serum biochemical tests (especially renal function)
- Skeletal muscle enzymes (cardiac isoenzymes)
- Serum troponin concentration
- Red blood cell potassium
- Fractional excretion of potassium

Echocardiogram/Doppler echocardiogram

- Examine for cardiomegaly or reduced myocardial function
- Identify predisposing cardiac lesions and abnormal flow

Serum/plasma concentrations of cardioactive drugs

- Serum digoxin concentration
- Plasma quinidine concentration

Response to medications

Modified from Bonagura JD: Clinical evaluation and management of heart disease, *Equine Vet Educ* 2:31-37, 1990.

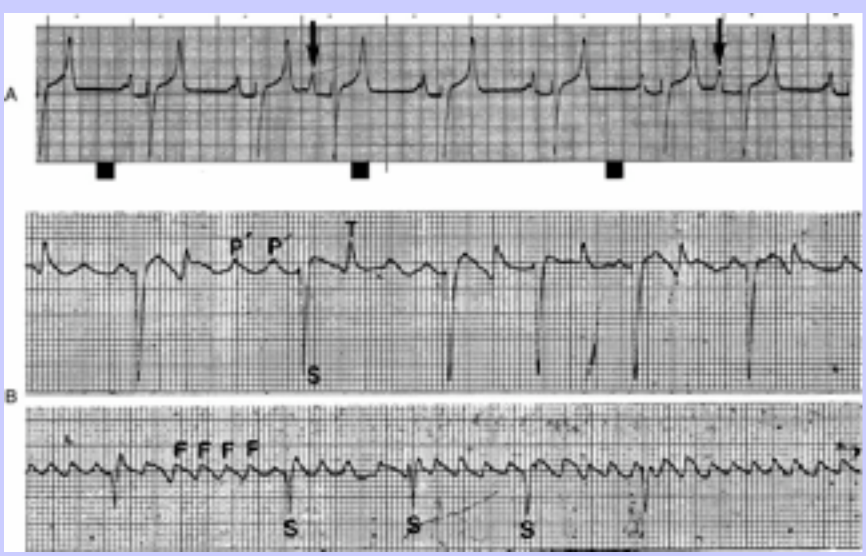
Figure 8-52 Sinus rhythms. **A,** Sinus bradycardia *(top)* and tachycardia *(bottom)*. Base-apex lead recorded at 25 mm/sec. **B,** Sinus arrhythmia with second-degree atrioventricular block *(arrows)*. An ambulatory electrocardiogram is shown; transthoracic leads recorded at 25 mm/sec.

Sinus bradycardia is generally a benign rhythm in standing horses; however, when occurring during sedation or anesthesia, sinus bradycardia or arrest may cause CO to decrease and result in significant hypotension. Treatment of symptomatic sinus bradycardia can include the infusion of catecholamines (dobutamine, dopamine, epinephrine) or the administration of anticholinergic drugs (atropine, glycopyrrolate) (see Table 8-6). One can infuse dopamine or dobutamine to increase heart rate, contractility, and arterial blood pressure; however, reflex atrioventricular block may develop in some horses.[187,191,212,257] Excessive administration of catecholamines causes sinus tachycardia and ectopic beats. Anticholinergic drugs may not be effective in the setting of anesthetic-induced depression of sinoatrial function, particularly if vagal efferent traffic is low. Gastrointestinal complications including ileus and colic may develop after anticholinergic drug therapy; thus one should not choose it for trivial rate problems.

8.11.2 ATRIAL ARRHYTHMIAS

Rhythms originating in the atria are common. These disturbances often develop as functional disorders with no overt structural cardiac lesion. Autonomic imbalance (including high sympathetic activity), hypokalemia, β-agonists, infections, anemia, and colic can cause atrial premature complexes. Of course, atrial rhythm disturbances are common with structural lesions of the valves, myocardium, or pericardium. Myocarditis after viral or bacterial infection may precipitate atrial arrhythmias in some horses. Atrial premature complexes can precipitate sustained atrial arrhythmias such as atrial tachycardia, atrial flutter, and atrial fibrillation. The large size of the equine atria and the frequent presence of microscopic atrial fibrotic lesions predispose the horse to these sustained arrhythmias. The high resting vagal tone present in most horses serves to shorten the duration of 432
the action potential of atrial myocytes and also facilitates development of sustained atrial tachyarrhythmias, 433
which probably depend on reentry.

Figure 8-53 Electrocardiograms with atrial rhythm disturbances. **A,** Premature atrial complexes *(arrows)*. The premature P waves of different morphology, the slightly prolonged P-R interval indicating atrioventricular nodal refractoriness, and the normal-appearing QRS complex indicating a supraventricular origin are notable. A slight conduction aberrancy exists in the second premature QRS complex (see also Figure 8-15). **B,** Sustained atrial tachyarrhythmias. The top picture shows atrial tachycardia with rapid, regular P waves *(P')* and a variable ventricular rate response to conducted P waves. The base-apex lead recorded at 25 mm/sec. The lower trace shows atrial flutter *(F)* with variable ventricular response *(S)*. Lead 3 recorded at 25 mm/sec.



Atrial arrhythmias are the most common abnormal rhythms detected in horses (Figures 8-53 and 8-54).[*] Atrial premature complexes are the least complex of these rhythm disturbances and may be clinically insignificant or associated with exercise intolerance or other signs of cardiac disease. In contrast, atrial tachycardia, atrial flutter, and atrial fibrillation are likely to be clinically significant. The overall importance of atrial premature complexes is often difficult to ascertain. Routine ECG rhythm strips recorded from more than 950 horses and interpreted by one of the authors (Bonagura) indicated that atrial arrhythmias, overall, were present in less than 3% of the horses studied. However, when one of us (Reef) examined clinically normal horses by Holter monitor, atrial premature complexes were present in 28% of the horses. Thus the incidence of atrial arrhythmias appears to depend not only on the population examined but also on the methods used. Clearly, one should assess these rhythm disturbances in light of other clinical findings.

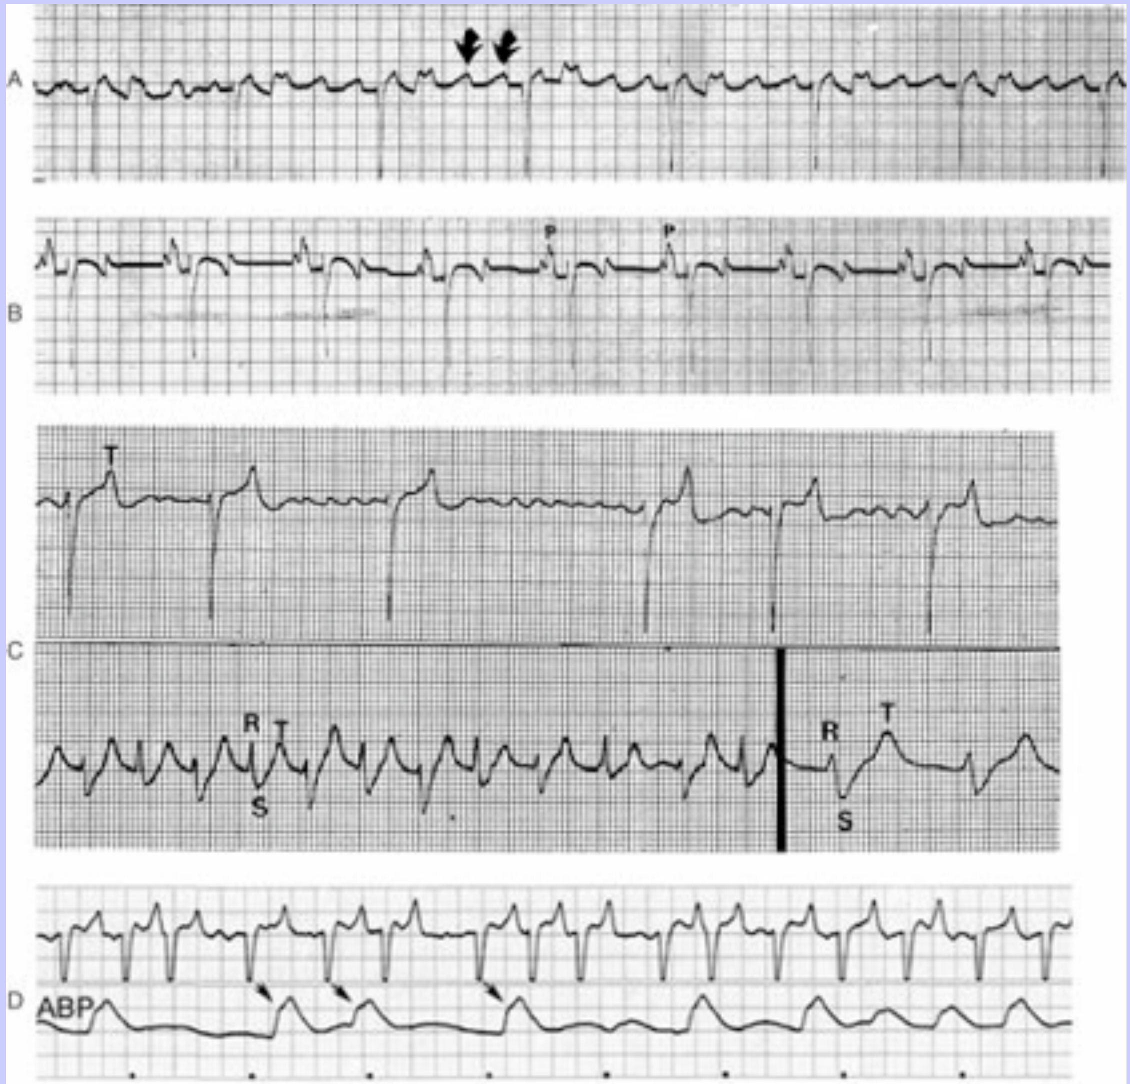
8.11.3 ATRIAL PREMATURE COMPLEXES

The clinician can detect atrial premature complexes by auscultation and document them by ECG. Auscultation usually reveals a regular sinus rhythm that is interrupted by an obviously premature beat (see Table 8-1). Premature atrial contractions may be interpolated fully (the regular sinus rhythm continues after the premature 433
atrial contraction) or a pause may occur, if the sinus node is reset. The ECG is characterized by a premature 435
(usually narrow) QRS complex, which is preceded by an abnormal, premature P wave that is often buried within the preceding T wave. Often the P-R interval is longer than normal (physiologic first-degree atrioventricular block), and in other cases the ectopic P wave is nonconducted (physiologic second-degree atrioventricular block) (see Figure 8-53). One must take care not to overdiagnose atrial premature complexes. Sinus arrhythmia and sinus bradycardia often lead to variations in the P-P intervals, and often a “wandering atrial pacemaker” gradually alters the P wave morphology. Exercise or excitement abolishes such physiologic rhythms.

Figure 8-54 Atrial arrhythmias. **A** and **B,** Successful conversion of atrial fibrillation using a combination of digoxin and quinidine (see text for details). **A,** Incomplete conversion of atrial fibrillation to atrial tachycardia with rapid, regular atrial activity *(arrows)*. **B,** Conversion to normal sinus rhythm during combination therapy. **C,** Quinidine toxicosis can be manifested as abnormalities on the electrocardiogram. In this horse, atrial fibrillation (*top*; base-apex lead recorded at 25 mm/sec) was not converted. The lower recording shows persistent atrial fibrillation with a rapid atrioventricular conduction response, electrical alternans, and widening of the QRS complex (lead 2 recorded at 25 mm/sec; right panel, at 50 mm/sec). The rapid rate response is related to the vagolytic effect of quinidine. The electrical alternans is common with regular supraventricular tachycardias with rapid ventricular response rates; this finding indicates varying conduction into the ventricle. The widened QRS is a sign of quinidine toxicosis. An idiosyncratic reaction leading to polymorphous ventricular tachycardia also has been recognized (see Figure 8-56). **D,** Hemodynamic consequences of increasing ventricular response rate in atrial fibrillation. The short QRS-QRS intervals do not generate effective arterial pulsations recorded in the arterial blood pressure *(ABP)* tracing, which is related to inadequate ventricular filling time during short cycles. Pulse deficits are detectable by physical examination.



As a general rule, atrial premature complexes are more likely to be clinically significant in the following circumstances: if they (1) are frequent at rest, (2) are associated with nonsustained or sustained runs of atrial tachycardia, (3) are related to poor performance (while other causes are excluded), (4) precipitate paroxysmal atrial flutter or fibrillation, or (5) develop along with other signs of cardiac disease. Documentation of atrial arrhythmias *during* exercise may be critical for determining if paroxysmal atrial tachycardia or fibrillation is likely to be the cause of poor performance.[354] One must use clinical judgment, however, because supraventricular premature complexes are most likely to occur in the immediate postexercise period, probably associated with autonomic imbalance. If these postexercise arrhythmias are not associated with clinical signs and are not detected during exercise, they are unlikely to be clinically significant. Cardiac rhythm monitoring during exercise may be necessary to be certain. In summary, routine electrocardiography, clinical chemistry, hematology, echocardiography, exercising electrocardiography, postexercise electrocardiography, and continuous 24-hour electrocardiographic monitoring may play a role in the complete evaluation of a horse suspected of having intermittent cardiac arrhythmias.

One generally does not treat isolated atrial premature complexes. The hemodynamic consequences of these rhythm disturbances is minor, unless sustained abnormal activity develops. Consideration of antiarrhythmic therapy might be appropriate if one documents frequent atrial extrasystoles as precipitating atrial fibrillation. In such cases, one may contemplate using quinidine or procainamide (though both therapies are impractical for chronic use) or digoxin. Although digoxin is easiest to administer long term, the effectiveness of such treatment has not been established except in the setting of CHF. Maintenance of normal serum potassium may be important in suppressing atrial ectopic activity. In cases of suspected immune-mediated myocarditis, one might consider antiinflammatory doses of dexamethasone as empirical therapy.

8.11.4 ATRIAL TACHYCARDIA

Atrial tachycardia, a sustained, ectopic, abnormal atrial tachyarrhythmia, occurs infrequently. Atrial tachycardia may be sustained or nonsustained (paroxysmal) and is precipitated by an atrial premature complex. The atrial rate is rapid and regular; however, because many of the ectopic P waves are blocked physiologically in the atrioventricular node, an irregular ventricular rate response often results. Atrial rates of 120 to 300 beats/min are typical in horses with sustained atrial tachycardia. At lower atrial rates, 2:1 atrioventricular conduction may yield a regular, relentless heart rate. At the higher atrial rates, the rhythm may be indistinguishable from atrial flutter. Differentiation of atrial tachycardia from flutter is not critical because both arrhythmias carry the same clinical significance and are treated identically. One recognizes sustained atrial tachycardia most often during treatment of horses with quinidine sulfate. Before conversion of atrial fibrillation to sinus rhythm, one may observe atrial tachycardia; thus this rhythm indicates a partial therapeutic effect of quinidine on the atrial myocardium. When this atrial tachycardia occurs as an isolated finding, one should suspect structural or underlying myocardial disease and should consider the horse predisposed to development or recurrence of atrial fibrillation. Treatment is the same as that described for atrial fibrillation.

8.11.5 ATRIAL FLUTTER

Atrial flutter is even less common than atrial tachycardia and represents a form of atrial circuit movement or macro-reentry. The clinical circumstances and assessment of this rhythm disturbance are identical to those of atrial tachycardia. The ECG in atrial flutter is characterized by a rapid abnormal but regular atrial activity usually manifested as a saw-toothed ECG baseline. The atrial frequency often exceeds 300 beats/min. The RR intervals are usually irregular because of variable atrioventricular conduction, and fewer QRS and T complexes than flutter waves are present (see Figure 8-53). The ventricular rate depends on the refractory period of the atrioventricular node and on the strength of the atrial stimulus. Treatment of atrial flutter is similar to that for horses with atrial fibrillation.

8.11.6 ATRIAL FIBRILLATION

Atrial fibrillation is the most common atrial arrhythmia associated with poor performance and exercise intolerance.[*] CO at rest is normal in most horses with atrial fibrillation[474]; yet maximal CO during exercise is 435
limited because the atrial contribution to filling is most important at higher heart rates. Undoubtedly, the already 436
high LA pressure present in heavily exercising horses[481,482] is increased further by the loss of active atrial transport function. As expected, exercise intolerance is most common in high-performance horses (racehorses, advanced combined training horses, polo ponies, and some Grand Prix jumpers) and less common in show hunters and in pleasure, dressage, and endurance horses. Exercise-induced pulmonary hemorrhage, respiratory

distress, CHF, ataxia or collapse, and myopathy have been reported with atrial fibrillation; conversely, the arrhythmia often is detected as an incidental finding.[314]

Atrial fibrillation may be paroxysmal or sustained. Paroxysmal atrial fibrillation often is associated with a single episode of poor performance, with the horse often decelerating suddenly during a race. The arrhythmia usually disappears spontaneously within 24 to 48 hours. Paroxysmal atrial fibrillation may be associated with transient potassium depletion, particularly in horses treated with furosemide or bicarbonate solutions, and most often is unrelated to other clinical or echocardiographic abnormalities of cardiac disease. Sustained atrial fibrillation may be less common than paroxysmal atrial fibrillation but is easier to diagnose because the arrhythmia is sustained. A point of emphasis is that many horses with sustained atrial fibrillation have no other evidence of significant underlying cardiac disease. Box 8-11 summarizes those factors that interact in the prognosis of a horse with atrial fibrillation. Of these, CHF represents the overall worst prognostic indicator. Atrial fibrillation is most common in adult horses and has been reported infrequently in foals, weanlings, yearlings, or ponies. Several reports indicate a higher incidence in Standardbreds, Draft Horses, and Warmblood Horses compared with the general hospital population.

Atrial fibrillation also occurs commonly in horses with advanced mitral or tricuspid insufficiency or CHF. In these horses, treatment should aim at controlling CHF and resting heart rate with furosemide, an ACE inhibitor, and digoxin as opposed to quinidine conversion back to sinus rhythm.

Atrial fibrillation is characterized on auscultation by an irregular heart rhythm, variable intensity heart sounds, and an absent S_4 (see Table 8-1). Arterial pulses vary in intensity, and pulse deficits may be present. The ECG is characterized by an absence of P waves; instead, fibrillation or f waves occur in the baseline. These f waves may be coarse (large) or fine (small), and the number of atrial impulses per minute cannot be counted but usually exceeds 500. The QRS-T complexes are normal in morphology and duration, but ventricular rate response is irregular, although one may observe periodicity infrequently.[169] As for all atrial tachyarrhythmias the ultimate ventricular rate response depends on the refractory period of the atrioventricular node and the strength of the atrial stimuli. In the otherwise healthy horse in atrial fibrillation, vagal tone is high and sympathetic tone is low when standing; consequently, the ventricular rate is close to normal or slightly increased (30 to 40 beats/min). If sympathetic activity increases for any reason or if vagal activity is blocked (as occurs with quinidine sulfate therapy), the ventricular rate response increases as the atrioventricular nodal refractory period shortens. This explains the clinician's simple but useful dependence on measuring pretreatment, resting heart rate in horses with atrial fibrillation.[314,501] Because the horse with structural heart disease is more likely to require sympathetic support to maintain CO and arterial blood pressure, persistent resting tachycardia, higher than 60 beats/min, is associated with a poorer prognosis.

Laboratory studies in horses with atrial fibrillation are usually normal. Infrequently, a horse is found to have low serum potassium, fractional excretion of potassium, or red blood cell potassium. Chest x-rays are usually normal unless pulmonary disease is concurrent, and this study is not a high-yield procedure in horses without compatible signs of lung disease or structural heart disease. The echocardiogram is usually normal, unless valvular or ventricular myocardial disease is concurrent. Commonly an otherwise normal horse demonstrates a slightly reduced LV shortening fraction (usually 24% to 32%), which returns to normal once the horse has been converted to sinus rhythm.[418,632] This decrease in fractional shortening is probably multifactorial in origin but is related in part to decreased preload from loss of the atrial contribution to ventricular filling. Doppler studies are useful in evaluating horses with concurrent valvular disease.

One may give an excellent prognosis for conversion (>95% conversion rate) for horses with a heart rate of less than or equal to 60 beats/min, murmurs less than or equal to grade 3 out of 6, and atrial fibrillation of less than 4

months in duration.[501] Recurrences affect approximately 25% of these horses. Horses with longer duration of atrial fibrillation or significant other cardiac disease may be more difficult to convert to sinus rhythm (80% conversion) and have a higher recurrence rate (60% recurrence). Horses usually can return to training within 24 to 48 hours after conversion, once plasma quinidine concentrations are undetectable. One should evaluate carefully any horses with heart rates exceeding 60 beats/min for heart failure or structural disease and probably should not treat the horses with quinidine before a complete evaluation.

Conversion of atrial fibrillation to sinus rhythm using quinidine sulfate has been successful in many horses and using a variety of treatment plans (see Figure 8-54).[276,619,638] Box 8-11 summarizes general recommendations for therapy, including alternative treatments. Intravenously administered quinidine gluconate can be successful in conversion of horses with no other significant cardiac disease and atrial fibrillation of recent onset.[629] If this treatment is not successful or the suspected duration is longer than 1 month, one should attempt conversion with quinidine sulfate administered via nasogastric intubation at a dosage of 22 mg/kg every 2 hours until the horse converts or develops initial signs of toxicosis. One should consider toxicosis or a cumulative dose of 88 to 132 mg/kg the endpoints for therapy and if conversion has not occurred, one should obtain a plasma sample for determination of quinidine plasma concentration and should discontinue therapy temporarily for at least 6 hours. Therapeutic plasma quinidine concentrations for conversion from atrial fibrillation to sinus rhythm are 2 to 5 μg/ml. One should base subsequent quinidine sulfate administration on the most recent plasma concentration. The mean quinidine elimination half-life after an oral 10-g dose is 6.65 hours.[257,639] Thus after the loading regimen every 2 hours, one can prolong treatment intervals to every 6 hours (approximately every half-life) and can continue these treatment intervals until the horse shows toxic signs or converts to sinus rhythm, or the owner elects to discontinue treatment. If conversion to sinus rhythm has not occurred after 24 hours of therapy, one may add digoxin at 0.0055 to 0.011 mg/kg orally twice a day to the treatment regimen for 24 to 48 hours. As in other species, a digoxin-quinidine interaction effectively can double the serum concentration of digoxin.[640] Thus combination therapy beyond 24 hours should continue only with drug level monitoring of the serum digoxin and consideration of using the lower end of the digoxin dosage range. Even horses that do not convert on the standard administration regimen every 2 hours may convert after the initiation of an every-6-hour interval or the combined use of quinidine and digoxin. The value of using such a treatment plan every 6 hours is reaching of steady-state levels, having sufficient time to attain myocardial concentrations, and lower frequency of quinidine toxicity compared with the every-2-hour regimen.

8.11.6.1 BOX 8-11 MANAGEMENT OF ATRIAL FIBRILLATION

8.11.6.1.1 General Examination of the Horse

(see Box 8-4)

8.11.6.1.2 Identification of Negative Prognostic Factors

Congestive heart failure (CHF)

Consistently elevated resting heart rate

Dilated cardiomyopathy

Mitral, tricuspid, or aortic valve regurgitation with cardiomegaly

Long history of atrial fibrillation

Prior bouts of atrial fibrillation

Unresponsive to therapeutic doses of quinidine

8.11.6.1.3 Horse Without Heart Failure

8.11.6.1.3.1 Recommended method: initial oral dosing at 2-hour intervals

- Initiate therapy with quinidine sulfate via nasogastric tube, 22 mg/kg body mass every 2 hours to a cumulative dose of 88 to 132 mg/kg, or until conversion or toxicosis occurs.
- When the aforementioned treatment fails to achieve conversion to normal sinus rhythm, continue quinidine therapy at a dose of 22 mg/kg every 6 hours for an additional 2 to 4 days, monitoring plasma quinidine concentration.
- Administer digoxin concurrently during quinidine therapy in the following situations: (1) if the vagolytic effect of the drug causes significant acceleration in ventricular rate response, (2) if resting heart rate exceeds 90 to 100 beats/min, (3) if the horse exhibits low resting vagal tone (e.g., a nervous animal), or (4) beginning on the second day of quinidine therapy if conversion has not yet occurred.[*]
- An oral maintenance dose range of digoxin for control of ventricular rate response in atrial fibrillation is 1.1 to 1.5 mg/100 kg body mass every 121 hours[†]; alternatively, administer an intravenous maintenance dose of digoxin at 0.22 to 0.375 mg/100 kg body mass every 12 hours.[†]
- Monitor plasma levels of quinidine if possible; therapeutic levels associated with conversion to normal/sinus rhythm are 2 to 5 µg/ml.
- Monitor plasma levels of digoxin to avoid digoxin toxicity.

8.11.6.1.3.2 Alternative therapy: IV dosing

- Administer quinidine gluconate 1 mg/kg intravenously every 5 to 10 minutes to a maximum of 10 mg/kg cumulative dose.
- This treatment is used most frequently for conversion of atrial fibrillation of recent onset (<7 days), during anesthesia, or when nasogastric delivery is difficult or impossible.

8.11.6.1.3.3 Toxicosis

- Monitor the electrocardiogram for response and toxicosis (increasing ventricular rate response, increasing QRS duration, or proarrhythmic effect causing ventricular tachycardia).
- If toxicosis develops (see text), discontinue therapy until all signs resolve, and initiate oral therapy using the every-6-hour method as described earlier.
- Consider a 24-hour Holter electrocardiogram on the day after conversion to evaluate for recurrent atrial arrhythmias.

8.11.6.1.3.4

Rest the horse

For 1 to 2 weeks if possible (in racing horses, training can begin 48 hours after conversion).

8.11.6.1.3.5

Reevaluate the horse

For atrial arrhythmias, before starting training and during training.

8.11.6.1.4

Horse with Heart Failure

- Low probability for return to serious work; however, successful therapy may permit breeding or keeping the animal as a pet.
- Establish diuresis with furosemide (1 mg/kg intravenously or intramuscularly every 12 hours) as needed to control edema. Continue maintenance furosemide therapy at 0.5 to 1 mg/kg per os every 12 to 24 hours; titrate the daily dose to effect.
- Digitalize the horse to control heart rate and treat heart failure.

  Use an intravenous maintenance dose for treatment of CHF at 0.22 mg/100 kg body mass every 12 hours[†] to initiate therapy until clinical signs of CHF have been controlled; alternatively, begin therapy using the oral maintenance dose below.

  Administer an oral maintenance dose of 1.1 to 1.75 mg/100 kg body mass every 12 hours[†] chronically.
- Prescribe an angiotensin-converting enzyme inhibitor such as enalapril (see text).
- Monitor the serum digoxin concentration (therapeutic trough levels are 1 to 2 ng/ml).
- Monitor serum electrolytes, blood urea nitrogen, and serum creatinine.
- Monitor the resting heart rate, clinical signs, and electrocardiogram.

* The clinician should consider the potential for quinidine-digoxin drug interaction elevating the serum digoxin level (see text).

† When a dosage range is given, generally begin at the lower end of the dose.

Conversion of horses with atrial fibrillation generally results in a return to their previous performance level.[314,501] Horses with repeated episodes of atrial fibrillation often are converted numerous times with quinidine sulfate treatment. Most horses that experience a recurrence of atrial fibrillation do so within 1 year of initial conversion, but periods as long as 6 years have occurred between episodes of atrial fibrillation in some horses. If the duration of sinus rhythm becomes shorter, repeated treatments may no longer be practical, and a career change may be indicated. Some horses eventually become refractory to quinidine sulfate, probably because of the progressive atrial fibrosis or underlying myocardial disease.

One should perform careful clinical and continuous electrocardiographic monitoring on horses with atrial fibrillation during conversion to sinus rhythm and should monitor and compare the QRS duration with the pretreatment QRS duration before administering each additional treatment. Prolongation of the QRS duration to greater than 25% of the pretreatment value is an indication of quinidine toxicity and should prompt discontinuation of therapy. The simplest ECG change is an acceleration of atrioventricular nodal conduction related to the vagolytic effect of quinidine. Rapid supraventricular tachycardias with ventricular rate responses of 300 beats/min have been observed in several horses receiving quinidine sulfate. These horses have been treated intravenously with digoxin at 0.002 mg/kg to slow the ventricular response rate, replacement fluids to improve perfusion, sodium bicarbonate at 1 mEq/kg to bind any free plasma quinidine, and if needed, a phenylephrine drip to restore blood pressure if hypotension is critical. Ventricular arrhythmias (torsades de pointes, multiform ventricular tachycardia, and ventricular complexes) also have been detected with quinidine toxicosis (see Figure 8-54). Intravenously administered sodium bicarbonate also is indicated in these horses to bind free circulating quinidine, whereas intravenously administered magnesium sulfate (up to 25 g in a 450- to 500-kg horse) is the treatment of choice for quinidine-induced ventricular arrhythmias. One also may use lidocaine hydrochloride if needed, starting with an intravenous bolus of 0.5 to 1.5 mg/kg given slowly intravenously.

Clinical markers of quinidine toxicosis include ataxia, colic, and nasal edema causing upper respiratory tract stridor. Most toxic reactions to quinidine sulfate are associated with higher plasma concentrations of the drug (>5 μg/ml) and can be avoided with careful clinical and electrocardiographic monitoring. Many of the adverse effects of quinidine administration are idiosyncratic reactions. These adverse effects should prompt discontinuation of therapy or altering of treatment intervals. Depression and paraphimosis occur in most horses treated with quinidine but disappear with the discontinuation of the drug. Diarrhea often develops with the administration of higher doses of quinidine, but this sign also disappears with discontinuation of the drug. Convulsions, hypotension caused by vasodilation, CHF, laminitis, urticaria, and sudden death also have been reported 438
associated with quinidine sulfate administration, although these fortunately are rare. Tachycardia exceeding 100 439
beats/min is an adverse idiosyncratic reaction that one should avoid if at all possible. Particularly nervous horses or those prone to the vagolytic effects of quinidine may benefit from pretreatment with digoxin at 0.011 mg/kg orally twice daily to blunt the ventricular rate response. When the ventricular rate response exceeds 100 beats/min in any horse undergoing quinidine sulfate conversion, one should consider digitalization, particularly if no other signs of quinidine toxicosis occur (indicating an excessive plasma concentration).

Future treatments of atrial fibrillation or flutter in horses might involve overdrive pacing of the atria or intracardiac mapping and radiofrequency ablation of tissue.[638] Electric cardioversion has been used in a limited number of horses to induce sinus rhythm,[641] but such therapy requires general anesthesia. These may represent future approaches to therapy but currently are considered experimental.

8.11.7 JUNCTIONAL ARRHYTHMIAS

Cardiac arrhythmias that originate within the atrioventricular conducting tissues, the ventricular specialized conducting tissues, or myocardium are classified as junctional (atrioventricular nodal or bundle of His) or ventricular in origin. Unlike sinus or atrial arrhythmias, a conducted P wave does not precede these arrhythmias. Junctional and ventricular rhythms often lead to dissociation between the sinoatrial (P wave) activity and that of the ventricle (QRS-T), resulting in atrioventricular dissociation.[359] Atrioventricular dissociation in these cases

develops because the premature atrioventricular junctional or ventricular depolarization causes interference with the conduction of normal sinoatrial impulses.

Distinguishing between junctional and ventricular arrhythmias and determining the exact location of the abnormal impulse formation may be difficult. One sometimes can make the differentiation of junctional and ventricular rhythms by inspecting the QRS complex. Junctional impulses are more likely to result in a narrow, normal-appearing QRS complex with normal initial activation and electric axis, because they originate above the ventricular myocardium. Complexes of ventricular origin, by contrast, are conducted abnormally and more slowly, resulting in a widened QRS, an abnormal QRS orientation, and abnormal T waves. However, junctional tachycardias may be conducted aberrantly, resulting in a bizarre and wide QRS complex. When sustained, both types of rhythms cause atrioventricular dissociation with an independent atrial rhythm superimposed on the ectopic ventricular rhythm. The normal heart contains potential cardiac pacemakers within the atrioventricular and ventricular specialized tissues. These potential pacemakers may become manifest during periods of sinus bradycardia or atrioventricular block. Such complexes are termed *escape complexes* or, if the junctional or ventricular complexes are linked together, *escape rhythms*. Escape rhythms are characterized by slow ventricular rates, often in the realm of 15 to 25 beats/min. These normal pacemakers may be enhanced under certain conditions, including the administration of anesthesia or catecholamines. Preanesthetic drugs such as xylazine and detomidine and anesthetic drugs (halothane) suppress sinoatrial function, resulting in sinus bradycardia or periods of sinus arrest while enhancing the effects of catecholamines on latent junctional and ventricular pacemakers (Figure 8-55). Such accelerated idioventricular (or idionodal) rhythms generally have little clinical significance other than to prompt the reduction of anesthetic dosages or promote administration of vagolytic drugs to increase the sinoatrial rate. Specific antiarrhythmic drug suppression of escape rhythms is generally not necessary and is contraindicated because these rhythms serve as rescue mechanisms for the heart.

Junctional complexes that arise early relative to the normal cardiac cycle are designated as *premature* junctional complexes. These complexes may occur as single or repetitive events and can resemble ectopic rhythms that might originate in the atria. Repetitive ectopic complexes that occur in short bursts or runs are termed *nonsustained* or *paroxysmal tachycardias*. Sustained junctional tachycardias also may occur and can lead to CHF.

The clinical significance of an occasional junctional premature complex is difficult to ascertain. Persistent or repetitive junctional or ventricular rhythms indicate heart disease, systemic disease, or a drug-induced abnormality of cardiac rhythm. The best management choice is uncertain inasmuch as some junctional rhythms behave more like atrial tachyarrhythmias, whereas others cause atrioventricular dissociation and appear to act like ventricular ectopic impulses. Because the mechanism responsible for junctional tachycardias can be abnormal automaticity or reentry (circuit) movement using the atrioventricular node, empirical therapy usually is required to control sustained arrhythmias. If atrioventricular dissociation is obvious, then quinidine would seem a reasonable first choice. If the mechanism is uncertain but is clearly supraventricular, then intravenously administered digoxin, verapamil, or propranolol may silence the rhythm or slow the rate.

8.11.8 VENTRICULAR ARRHYTHMIAS

Ventricular arrhythmias are less common than atrial arrhythmias but are more likely to be associated with underlying cardiac disease or a multisystemic disorder.[*] One may observe ventricular arrhythmias with severe toxemia or sepsis or primary gastrointestinal disorders including proximal enteritis and large bowel disorders; with electrolyte (potassium, magnesium) or metabolic disorders, hypoxia, or ischemia; or associated with halothane anesthesia. In particular potassium, magnesium, and calcium activities can affect myocardial 439

electrophysiology.[650] Drugs, myocardial toxins such as the ionophores, viral or bacterial myocarditis, 441

endocarditis, or pericarditis may lead to significant ventricular arrhythmias. The approach to the horse with ventricular arrhythmias should emphasize ruling out the noncardiac causes, correcting them (if possible), and then following if necessary with a complete cardiovascular examination, including electrocardiography and echocardiography. One should consider evaluating cardiac isoenzymes to identify cardiac injury, although separating primary from secondary causes of cardiac isoenzyme elevation may be difficult (see Box 8-10). Ventricular ectopic rhythms are classified as indicated in Box 8-9.

Figure 8-55 Ventricular extrasystoles (see also Figure 8-15). **A,** The ectopic complex *(arrow)* is premature and abnormal in morphology. A compensatory pause follows the extrasystole because the next sinus P-wave is blocked in the atrioventricular node. The effect of the premature complex on arterial blood pressure in the lower tracing *(arrow)* is noticeable. **B,** Ventricular rhythms. The top tracing demonstrates an idioventricular tachycardia in a postoperative gastrointestinal surgery case. Sinus complexes *(arrow)* are followed by ventricular ectopic beats at varying rates (base-apex lead recorded at 25 mm/sec). The lower tracing demonstrates atrioventricular dissociation caused by a sustained high ventricular (or junctional) ectopic rhythm. The atria are discharged independently by the sinus node (*arrowheads*; lead 2 recorded at 25 mm/sec).

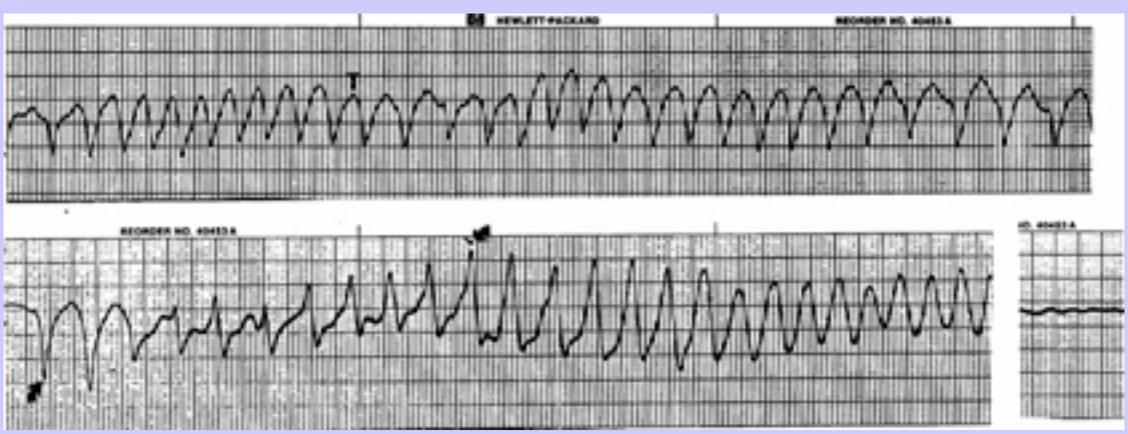
* References 177, 310, 359, 391, 412, 582, 584, 642–649.

8.11.9

VENTRICULAR PREMATURE COMPLEXES

Ventricular premature complexes are characterized by an ectopic, premature complex usually followed by a compensatory pause, because the next sinus impulse is blocked by the refractory atrioventricular conduction system. If the sinus rate is slow or the ventricular premature depolarization is coupled closely with the preceding normal sinus beat, the premature complex may be interpolated between two normal beats. Ventricular ectopic impulses are characterized by QRS and T waves that are wide and often bizarre in appearance (Figure 8-56). Of course, the premature QRS bears no relationship to any preceding P waves, though genesis of ventricular ectopics may depend on underlying cardiac cycle length. The morphology of the ventricular premature complex may be uniform or multiform. The relationship of a ventricular extrasystole to the preceding sinus QRS-T is expressed by the coupling interval between them. Often the coupling interval is fixed, although it may vary minimally[648] or considerably in cases of ventricular parasystole. A short coupling interval may place the ectopic QRS on the preceding T wave, a phenomenon called *R on T* and related experimentally to increased ventricular vulnerability for fibrillation. Ventricular premature complexes occurred in 14% of clinically normal horses during routine 24-hour continuous electrocardiographic monitoring.[310] The distribution pattern of ventricular ectopics may include haphazard distribution, bigeminy, couplets (pairs of ventricular premature complexes), or runs of ventricular ectopics. Runs of accelerated ventricular rhythm, usually developing at slow heart rates, are common in horses with ventricular ectopic activity. Infrequently, protected, totally independent ventricular rhythms typical of parasystole are recorded by Holter ECG. Runs of ventricular ectopics at a rapid rate—ventricular tachycardia—are more likely to be hemodynamically and electrically unstable, particularly when they develop at rates faster than 100 beats/min (see the following discussion).

Figure 8-56 Sustained, rapid ventricular tachycardia *(top)* of varying rate that develops into a polymorphic ventricular rhythm with varying morphology complexes (torsades de pointes). The horse died of cardiac arrest *(lower right panel)*. The arrows indicate QRS complexes of varying polarity (25 mm/sec).

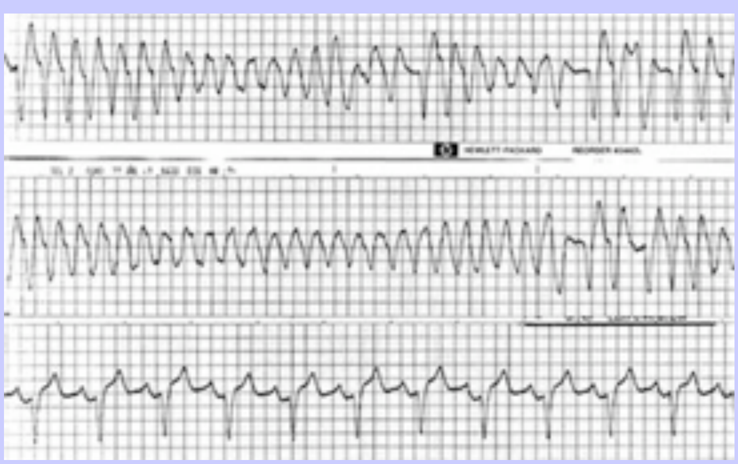


On identifying premature ventricular beats by auscultation, one should obtain an ECG and should undertake a workup similar to that outlined in Box 8-9. Occasional premature ventricular complexes, as with occasional supraventricular premature complexes, may be clinically insignificant and not require treatment. Rest is highly recommended for horses with frequent ventricular premature complexes. In the majority of horses with premature ventricular complexes, the arrhythmia seems to resolve spontaneously after 4 to 8 weeks of rest. The 441
horse then may be able to return successfully to its prior performance level. Antiarrhythmic therapy is usually 442
successful in abolishing ventricular premature complexes, but most complexes return when the antiarrhythmic agent is discontinued, unless the underlying problem has been resolved. Dexamethasone and other antiinflammatory drugs also may be helpful in abolishing ventricular premature complexes, but their use is controversial and they certainly should not be administered to horses with a recent or current infection.

8.11.10 VENTRICULAR TACHYCARDIA

Ventricular tachycardia is an ectopic ventricular rhythm characterized by a regular or irregular ventricular rate (Figure 8-57; see also Figure 8-56). Ventricular tachycardia is recognized clinically by the increased heart rate, often exceeding 100 beats/min, and the loud, sometimes booming heart sounds one may detect. Arterial pulse intensity is typically weak or variable. Multiform ventricular tachycardia is characterized by an irregular rhythm and usually is associated with more clinical signs of cardiovascular disease than uniform (unifocal) ventricular tachycardia. With multiform ventricular tachycardia, heart sounds are more likely to vary in intensity and arterial pulses are likely to be abnormal. One may detect jugular pulsations caused by atrioventricular dissociation. Syncope is associated with higher rates of ventricular tachycardia (180 beats/min or higher). Respiratory distress and pulmonary edema may develop from systolic and diastolic dysfunction. Sustained junctional or ventricular tachycardias (>120 beats/min) may lead to CHF.[582]

Figure 8-57 Polymorphous ventricular tachycardia following administration of quinidine sulfate for attempted conversion of atrial fibrillation. In this case normal sinus rhythm was established *(lower tracing)* following treatment with lidocaine, bicarbonate (to facilitate elimination of quinidine), and phenylephrine (administered to maintain arterial blood pressure).



Ventricular tachycardia may be life threatening if one detects R on T complexes; the arrhythmia is rapid (>180 to 200 beats/min); multiform ventricular tachycardia is detectable; or polymorphic tachycardia with torsades de pointes is present. The horse may require immediate treatment for cardiovascular collapse.[619] Intravenously administered lidocaine or quinidine usually is chosen for emergencies, although administration of either drug has been associated with side effects, including sudden death. Quinidine is a myocardial depressant and vagolytic drug. Lidocaine causes central nervous system excitation; thus one should weigh the risks and benefits of treatment carefully. However, recent studies of lidocaine indicate that boluses and infusions can be well tolerated in horses and causes minimal hemodynamic or electrophysiologic alterations at nontoxic doses.[547,548,651] In clinical practice one can use an initial bolus of 0.5 to 1.5 mg/kg and constant rate infusions of 25 to 50 mg/kg/min with careful observation for side effects. Quinidine gluconate at 1.1 to 2.2 mg/kg intravenously as a bolus and repeated up to 8.8 mg/kg is an alternative. Procainamide boluses of 2 mg/kg have electrophysiologic effects similar to quinidine but are less vagolytic and possibly have less gastrointestinal side effects. Magnesium sulfate 442
is an alternative antiarrhythmic that can be effective in normomagnesemic and hypomagnesemic horses. One 443
may administer magnesium sulfate intravenously in 2 g or larger boluses or as a rapid drip, up to a total dosage of 25 g per 450 to 500 kg. One may try other antiarrhythmics, including intravenously or orally administered procainamide[652] or propafenone,[653] in refractory ventricular arrhythmias (see Table 8-6).

A period of rest (4 to 8 weeks) followed by electrocardiographic and echocardiographic re-evaluation (including an exercising ECG) is indicated for follow-up of horses that have developed sustained ventricular tachycardia. A substantial number of these horses can be returned successfully to performance after treatment with antiarrhythmics or antiinflammatory drugs and rest.

8.11.11 CONDUCTION DISTURBANCES

Once formed, a cardiac electric impulse is conducted rapidly throughout the heart. The sequence of cardiac electric activation usually is dictated by the specialized conducting tissues in the atria, the atrioventricular node, the bundle of His, the bundle branches, and the Purkinje fiber system. This conduction system permits orderly activation of atrial and ventricular muscle and facilitates effective mechanical activity of the heart. A variety of conduction disorders are recognized, including sinoatrial nodal exit block, atrial standstill (usually caused by hyperkalemia), atrioventricular block, bundle branch block, and ill-defined ventricular conduction disturbances (Figures 8-58 and 8-59).[*]

Rarely, accelerated conduction occurs in the heart, which involves a pathway around the normally slow-conducting atrioventricular node and results in early excitation of the ventricles.[655] These syndromes are termed *preexcitation* and have various associated labels related to similar human disorders (e.g., Wolff-Parkinson-White). The preexcitation syndromes usually are characterized by short P-R intervals and widened QRS complexes. Some examples of these conduction disorders are described next.

8.11.11.1 Atrioventricular Conduction Block

Delays in atrioventricular conduction are the most common conduction disorders. These delays are classified as first-, second-, and third-degree (or complete). *First-degree atrioventricular block* occurs when the P-R (or PQ) interval exceeds a certain value (while the atrial impulse still transmits through the atrioventricular conduction system and activates the ventricle, causing a QRS). Some P waves are not conducted to the ventricles during *second-degree atrioventricular block,* which results in occasional P waves not followed by a QRS-T complex. *Third-degree* or *complete atrioventricular block* is characterized by an absence of atrial to

ventricular conduction. P waves are never followed by or related to QRS complexes, and to prevent ventricular asystole, a junctional or ventricular escape rhythm must develop below the level of the atrioventricular block.

First- and second-degree atrioventricular block are considered normal variations.[643] These rhythms most often are associated with high vagal tone and may occur with sinus bradycardia or sinus arrhythmia. One usually can abolish second-degree atrioventricular block with exercise, stress, or vagolytic drugs such as atropine or glycopyrrolate. Complete atrioventricular block indicates organic heart disease, severe drug toxicity, or rarely, high vagal activity. Generally speaking, third-degree atrioventricular block caused by vagal-efferent traffic is short-lived. Intraventricular conduction blocks, such as bundle branch block, are less common and more difficult to diagnose. Widening of the QRS complex and axis deviation are typical features. One also may find these abnormalities after atrial premature complexes, from overdosage with quinidine sulfate, or following supraventricular tachycardias with rapid ventricular response.

Sudden development of high-grade or complete atrioventricular block may require the administration of atropine or a catecholamine, or rapid transvenous insertion of a pacing wire into the right ventricle. Chronic third-degree atrioventricular block requires treatment with a pacemaker[433,656–659]; such a pacemaker has been placed successfully epicardially and transvenously in several horses and in miniature (Jerusalem) donkeys (Figure 8-60).

* References 161, 170, 176, 299, 392, 643, 654.

8.11.11.2 Preexcitation

Preexcitation, or accelerated atrioventricular conduction, has been reported sporadically,[655] but the clinical significance of this electrocardiographic abnormality has yet to be determined in this species. Ventricular preexcitation in human beings and in dogs often is caused by an anomalous conducting pathway around the atrioventricular node, which serves as a path for reentrant supraventricular tachycardias. These rhythm disturbances may cause hypotension and syncope. Whether preexcitation syndromes are important has yet to be determined. Nevertheless, ECG traces occasionally show evidence of ventricular preexcitation and are characterized by a P-QRS-T relationship but with an extremely short P-R interval, early excitation of the ventricle characterized by a slurring of the initial QRS complex (a delta wave), and an overall widening of the QRS complex.

8.11.11.3 Hyperkalemia

Hyperkalemia can cause significant depression of atrial, atrioventricular, and ventricular conduction and can 443
shorten ventricular repolarization. Serum potassium is most likely to be greatly elevated following oliguria, 444
rupture of the ureter, during shock, in foals with ruptured bladder and uroperitoneum, or after excessive intravenous potassium replacement. Experimentally, changes in the ECG are usually evident at potassium serum concentrations greater than 6 mEq/L, with severe changes evident when serum concentrations are between 8 and 10 mEq/L.[176,660–662] Broadening and flattening of the P wave are the most consistently observed change. Inversion or enlargement (tenting) of the T waves is also likely. One may note considerable widening of the QRS complex as near-lethal concentrations of potassium are approached. Ventricular asystole 444
or fibrillation can develop. The QT interval is not a reliable indicator of induced hyperkalemia, and other 446
electrolyte/acid-base alterations, including serum calcium and sodium, influence the effect of hyperkalemia on the heart.

Figure 8-58 Conduction disturbances. **A,** Second-degree atrioventricular block. Nonconducted P waves and varying P-R intervals are evident (base-apex lead recorded at 25 mm/sec). **B,** The tracings are from a horse with third-degree atrioventricular block. The upper strip demonstrates multiple blocked P waves. The lower tracing shows nonconducted P waves and ventricular escape complexes (base-apex lead recorded at 25 mm/sec). **C,** Permanent transvenous ventricular pacing in a miniature donkey with a complete atrioventricular block. A pacemaker spike *(arrow)* precedes each paced ventricular complex.

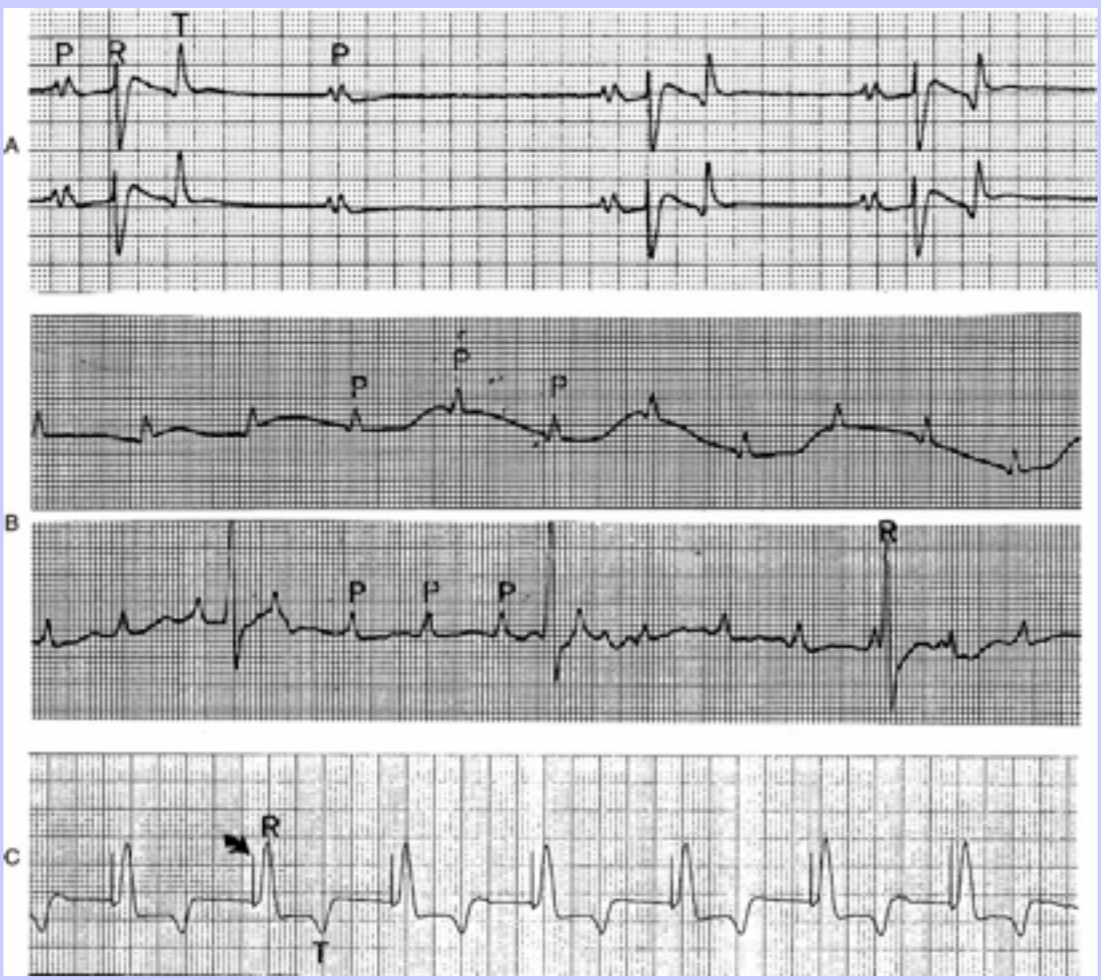


Figure 8-59 Conduction disturbances. **A,** Ventricular preexcitation. The short P-R interval *(arrow)* and small deflection in the P-R segment (delta wave) indicate an accessory pathway around the atrioventricular node with premature activation of a portion of the ventricle (delta wave and initial portion of the QRS). The large QRS and secondary T wave changes can be explained by the loss of normal cancellation of ventricular electrical forces. **B,** A sinus arrhythmia and intraventricular conduction disturbance. The sudden change and widening of the ventricular conduction pattern are notable, despite the consistent P-R interval and probably represent a bundle branch block, although this diagnosis is difficult to make in horses (base-apex lead recorded at 25 mm/sec). **C,** Hyperkalemia in a foal with a ruptured bladder. The top strip demonstrates atrial standstill (no P waves), significant widening of the QRS complexes, and large T waves with a shortened ST segment. The lower tracing shows the effects after initial medical therapy for hyperkalemia, which included treatment with saline and sodium bicarbonate. The normalization of the QRS complexes and the appearance of low-amplitude P waves *(arrows)* are notable. (Tracing courtesy of Ron Hilwig.)

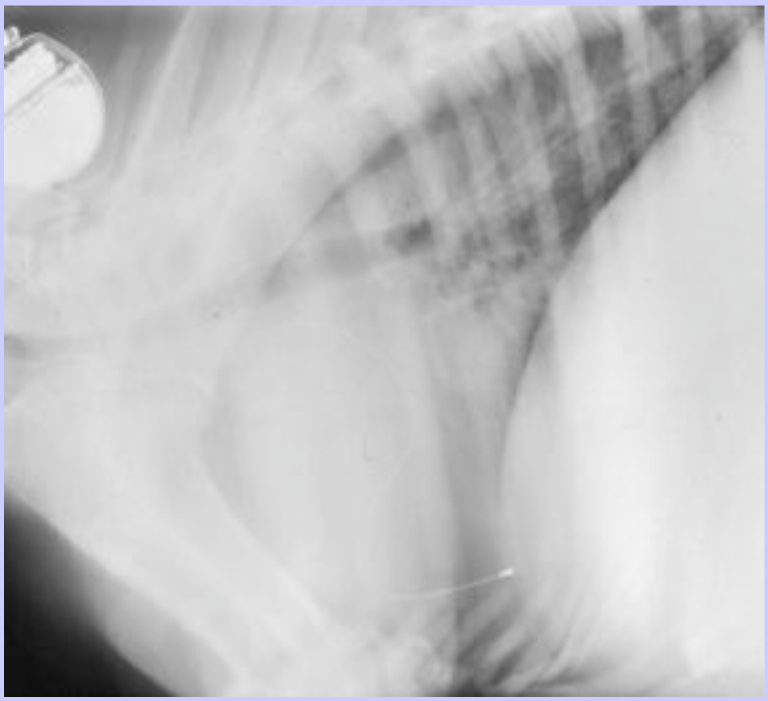
Figure 8-60 A lateral radiograph of a permanent transvenous pacing system in a miniature donkey. The pacemaker is evident at the upper left of the radiograph. The thin transvenous pacing wire extends from the device through the jugular vein and vena cava and into the right ventricular apex.



Therapy for hyperkalemia includes correction of the underlying problem; infusion of saline; and administration of sodium bicarbonate (initial dose 0.25 to 0.5 mEq/kg) and possibly calcium chloride. Although controversial, one may consider administration of regular insulin along with dextrose infusion in cases of life-threatening hyperkalemia. Potassium follows glucose intracellularly and lowers the extracellular potassium concentration.

9 CHAPTER 9 DISEASES OF THE MUSCULOSKELETAL SYSTEM

Jennifer M. MacLeay

The innate ability of the horse to learn and trust is a special attribute that allows human beings to take advantage of the extraordinary strength and agility of the horse. Horses have contributed to human life by assisting in agriculture, business, travel, and recreation. Although effective locomotion depends on the coordination ofmany body systems, movement ultimately depends on skeletal muscle. This chapter endeavors to review the many disorders that affect the muscular system of the horse.

9.1 Structure

Mammalian skeletal muscle consists of approximately 75% water, 18% to 22% protein, 1% carbohydrate, and1% mineral, with variable lipid content. Depending on the breed and type of horse, between 44% and 53% of the live weight of a mature 500-kg horse has been estimated to be muscle.[1] The myofiber, or individual muscle cell, is the fundamental building block of muscle, and each is a fusiform, multinucleated cell. Combined, myofibers constitute 75% to 90% of the volume of muscle. The myofibers are arranged in parallel along the length of the muscle such that the force of contraction is additive. The rest of the muscle tissue is made up of fibroblasts, capillaries, adipose cells, nerves, and connective tissue fibers. The composition of any muscle varies depending on the muscle surveyed and the overall fitness level, age, and breed of the horse. Muscles begin and end with tendons of various sizes, which attach the muscle to bone. Golgi tendon organs act as end organs of muscle sense andare found in the major tendinous origins and insertions. The nerve and blood vessels that supply an individual muscle typically enter near the midpoint of the muscle belly at a region called the neurovascular hilum. The nerve bundle splits off into individual nerves once it enters the muscle. A single nerve contacts several myofibers such that they contract in unison when stimulated (motor unit). A single nerve innervates each myofiber at a single point known as the motor end plate.

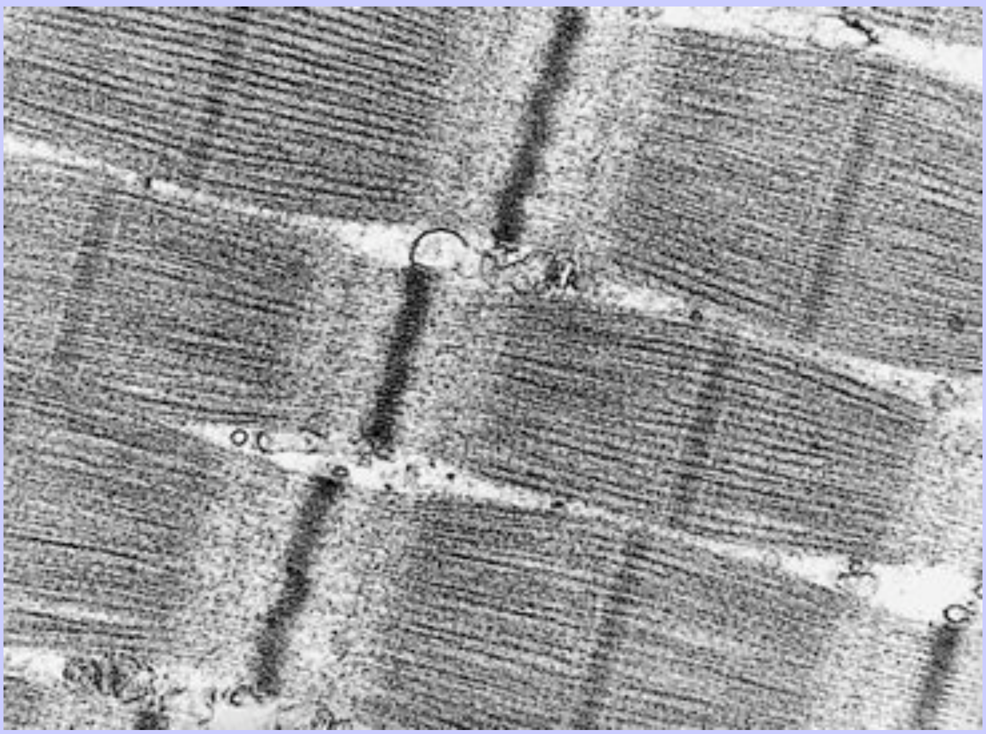
Each myofiber is bounded by a complex membrane called the sarcolemma, which invaginates into the muscle fiber at numerous points to form the T, or transverse, tubules. The T tubules terminate within each muscle cell in proximity to the sarcoplasmic reticulum of the cell, contacting the myofibrils between the A and I band twice within each sarcomere. The T tubule lies between two terminal cisterns of the sarcoplasmic reticulum. Together these three structures form the *triad*.

A basement membrane surrounds the sarcolemma and attaches closely to a layer of connective tissue called the endomysium. The endomysium is continuous with the perimysium, which surrounds groups or bundles of muscle fibers. The perimysium in turn is continuouswith the epimysium, which surrounds the entire muscle. Satellite cells, which consist of a simple cell membrane around a nucleus with a minimal amount of cytoplasm and few mitochondria, lie in shallow indentations on the myofiber surface between the sarcolemma and the basement membrane. Satellite cells give rise to new myofibers after rhabdomyolysis (dissolution of muscle fibers). The 461
nuclei of the satellite cells and mature myofibers are oriented to the long axis of the muscle fiber. The muscle fiber 462
nuclei lie at the periphery of the cells just within the sarcolemma.

Within each myofiber are parallel arrays of myofibrils, the basic contractile units of muscle. Myofibrils are composed of end-to-end stacks of rodlike structures or contractile units called sarcomeres. Each stack of sarcomeres forms a long filament, and arrays of filaments form the myofibrils. Sarcomeres are made up of the contractile proteins actin, myosin, tropomyosin, and troponin. Troponin is a complex of troponin T, troponin I, and troponin C, whereas myosin is made of heavy and light chains and a globular head that contains the myosin

adenosine triphosphatase (ATPase). Figure 9-1 shows an electron micrograph of several myofibrils. The alternating bands of light and dark are notable. The dark A band is composed of the thick myosin filaments and is transected by a darker line called the M line. Each myosin filament is surrounded by, and interdigitates with, six thin filaments composed of actin, tropomyosin, and troponin. Areas where the thin filaments are not overlapping with myosin form the lighter I band. The dark line running across the I band is called the Z line. A *sarcomere* is defined as the region between each Z line. At the Z lines, the protein α-actinin anchors actin. Because of the differing way these structures absorb light, the regular alternation of A bands and I bands in adjacent myofibrils produces the striated appearance characteristic of skeletal muscle fibers as viewed with light microscopy. Mitochondria fit into the small spaces around the myofibrils and produce the adenosine triphosphate (ATP) necessary for the contraction-relaxation cycle. The number, size, and shape of mitochondria vary depending onthe fitness of the individual and the muscle fiber type predominant within the muscle sampled.[2–4]

Figure 9-1 Electron micrograph of several muscle myofibrils. (×45,000.)



9.2 Muscle Contraction

To understand the pathophysiology of many muscle disorders, defining the sequential steps that lead to contraction is valuable. This process is known as excitation-contraction coupling.

9.2.1 EXCITATION

Excitation begins with the origination of a nerve impulse within the central nervous system. The impulse exits the spinal cord, travels along a motor neuron, and arrivesat the motor end plate of an individual myofiber. Motor end plates are located in deep primary clefts or folds of the sarcolemma. The nerve impulse arrives at the motor

end plate, releasing acetylcholine, which traverses the synaptic cleft and binds to nicotinic receptors. The binding of acetylcholine produces a conformational change in the nicotinic receptor, which results in the opening of ion channels, producing increased sodium and potassium conductance in the end plate membrane and causing depolarization and generation of an end plate action potential. The T tubule system propogates the action potential across the sarcolemma in all directions and carries it deep into the muscle fiber. Diffusion of acetylcholine from the receptors or hydrolysis by acetylcholine esterase causes depolarization to cease.

9.2.2 EXCITATION-CONTRACTION COUPLING

Coupling of excitation with contraction begins with the arrival of the action potential at the triad region, which causes opening of sodium channels embedded in the T tubule membrane and rapid influx of sodium into the cell. The rapid influx through the sodium channel results inthe change of polarity across the membrane that we associate with depolarization. As a result the inside of the sarcolemma becomes more positive relative to the outside of the membrane. Depolarization of the T tubule membrane triggers a voltage-gated calcium channel known as the dihydropyridine receptor, which also is located within the T tubule membrane. Activation of the dihydropyridine receptor triggers the closely related ryanodine receptorin the terminal cisternae of the sarcoplasmic reticulum, causing it to release calcium into the sarcoplasm.

9.2.3 CONTRACTION

Calcium released into the sarcoplasm binds to troponin C, resulting in a conformational change of the tropomyosin molecule and unmasking part of the actin filament responsible for binding to myosin: the G-actin monomer. With binding of myosin to the G-actin monomers, a 90-degree cross-bridge forms. As soon as the cross-bridge forms, myosin ATPase cleaves ATPto form adenosine diphosphate (ADP) and adenosine 462
monophosphate, resulting in another conformational change converting the 90-degree to a 45-degree angle. The 463
contractural force is believed to be generated bythe movement of the cross-bridge myosin head from a 90-degree to a 45-degree angle with a coincident sliding of the myofilaments relative to one another toward the center of the sarcomere. The hydrolytic products of ATP then detach from the myosin head. This enables the cycle to recommence, because the addition of new ATP to the myosin molecule results in the rapid dissociation of the actin and myosin filaments.[5,6] Sustained contraction occurs with the rapid repetition of this mechanicochemical cycle.[5]

Each sarcomere shortens in unison in successive ratchetlike movements comprised of multiple acts of relaxation and reengagement depending on the degree of shortening demanded by the nervous system. With input from the central nervous system to relax opposing muscles, the process of excitation-contraction coupling produces smooth coordinated movement.

9.2.4 RELAXATION

For the cell to relax and return to baseline polarity, the sarcoplasmic reticulum and the plasmalemma must reaccumulate calcium, thereby lowering the concentration of calcium in the sarcoplasm and the T tubule while sarcolemmal membranes begin to repolarize. Sarcoplasmic calcium concentrations decrease when calcium-magnesium ATPase pumps return calcium to the sarcoplasmic reticulum and sodium-potassium ATPase pumps move sodium extracellularly and potassium intracellularly. Energy-dependent reaccumulation of calcium by the sarcoplasmic reticulum results in the release of calcium from troponin C, restoration of the resting configuration

of the troponin-tropomyosin complexes, and ultimately disruption of the linkage between the myosin and actin filaments. Further details on muscle structure and contraction are available.[5–8]

An important note is that all of the processes necessary for relaxation are active, meaning they require energyin the form of ATP for them to occur. In the absence of ATP, actin and myosin remain engaged and the muscle remains in the shortened or contracted position known as rigor.

Several terms frequently are used when referringto the shortening of muscle in veterinary medicine. *Contraction* implies a shortening or tightening of the muscle that is initiated by the central nervous system. This electric activity is recorded readily using electromyography. A *contracture* is considered to be the contraction of a muscle because of abnormal activity within the muscle cell. A contracture originates within the muscle fiber itself and is therefore electrically silent on an electromyograph. Contractures occur in disorders characterized by muscle cramping such as polysaccharide storage myopathy or recurrent exertional rhabdomyolysis in which muscle shortening is typically electrically silent. The term *spasm* is more generic and may refer to a transient or sustained contraction or contracture. If a spasm is painful, the term *cramp* often is used. Fibrous tissue within a muscle may prevent complete stretching and shortening of a muscle, thereby limiting the range of motion of a limb or joint. Such occurs in fibrotic myopathy as described in a subsequent section.

9.2.5 SOURCE OF ENERGY FOR CONTRACTION

The hydrolysis of ATP provides the energy for contraction. When the phosphate bond of ATP is cleaved, the resulting by-products include ADP, inorganic phosphate, and energy. Numerous different processes within the muscle fiber can generate ATP and include glycogenolysis, glycolysis, Krebs cycle, oxidative phosphorylationby the electron transport chain, β-oxidation of free fatty acids, and purine nucleotide deamination. Energy also can be derived by cleavage of the phosphate bonds of creatine phosphate (or phosphocreatine) by the enzyme creatine kinase. (The frequently used term *creatine phosphokinase* is a misnomer.) Which pathways are most active depends on many factors, including the underlying muscle fiber composition, the number of motor units recruited, capillarization of the muscle, the underlying oxidative and glycolytic capacities of the muscle fibers, and the delivery of oxygen and other energy substrates to the muscle. In turn, the breed and age of the horse, the length or stage of exercise, the intensity of exercise, and the fitness level of the horse influence thesefactors.

The major energy sources for muscle include creatine phosphate, glucose, and free fatty acids. At the initiation of exercise, creatine phosphate serves as an immediate source of energy. However, these stores are small and serve only to provide a short-term energy source until glucose can be used to produce ATP. Glycolysis or the breakdown of glucose to carbon dioxide and water in the presence of oxygen liberates 38 moles of ATP per mole of glucose. Free glucose is present in small quantities within the sarcoplasm and can be transported into the cell from the blood. However, most of the glucose is stored in the muscle cell as the branched structure glycogen. Breakdown of glycogen, or glycogenolysis, results in the liberation of 37 moles of ATP per mole of glycogen. A large, extramuscular storage site of glycogen is the liver. With exercise, the liver begins to liberate free glucose into the blood. Muscle cells take up glucose by glucose transporters located in the cell membrane. Athletes that have exercised frequently over time develop a denser network of capillaries about each muscle cell to facilitate the delivery of oxygen and glucose to the cell and the removal of by-products. 463

464

Glycolysis and glycogenolysis are rapid processesand produce adequate energy for aerobic exercise. When exercise intensity increases and oxygen demand cannot be met, glucose is metabolized anaerobically. Anaerobic glycolysis yields 4 moles of ATP per mole of glucose and produces lactic acid as a by-product. The accumulation of lactic acid within the cell lowers the pH of the sarcoplasm, inhibits the function of many intracellular enzymes, and contributes to fatigue.

After a period of exercise (this varies between individuals but in many is after about 15 to 20 minutes of aerobic exercise) the muscle begins to rely more on the β-oxidation of free fatty acids than on glycolysis for the production of ATP. Depending on the free fatty acid, β-oxidation may produce up to 146 moles of ATP per mole of fatty acid. Small stores of fat are located within the muscle. However, most of the free fatty acids are liberated from body fat stores or the liver and are taken up by the muscle cell during exercise. The longer the aerobic exercise, the more energy is derived from metabolism of free fatty acids. This metabolism appears also to be influenced by diet. The higher the intake of fat, the more muscle appears to rely on free fatty acids for energy. The optimal ratio of fat in the diet of the horse respecting type and duration of exercise is yet to be determined.

The onset of fatigue during aerobic exercise is different from that during anaerobic exercise. During aerobic exercise, glycogen depletion, hyperthermia, and electrolyte depletion appear to be major factors. Whereas during anaerobic exercise, lactic acidosis and depletion of creatine phosphate and ATP appear to be important factors initiating fatigue. Accumulation of lactic acid withinthe muscle cell leads to decreased intracellular pH and inhibition of the enzymes important in glycolysis. A low intracellular pH also inhibits excitation-contraction coupling. In aerobic and anaerobic forms of exercise, eventual onset of myalgia and decreased motivation appear to be additional factors in fatigue.

When most forms of energy within the muscle are exhausted after extensive submaximal exercise or vigorous anaerobic exercise, the last source of energy withinthe cell is the formation of ATP from two molecules ofADP in a process known as the myokinase reaction. A by-product of this reaction is ammonia. Rising ammonia levels in the circulation are well correlated with the depletion of ATP within muscle. Depleted fibers may develop a painful, electrically silent contracture that is similar to rigor, and severely affected fibers may die. The death of muscle cells related to exercise is known as exertional rhabdomyolysis. Rhabdomyolysis often is assessed by the measurement of enzymes such as creatine kinase or lactate dehydrogenase that are released into theblood when muscle cells are severely stressed (the cell membranes become leaky) or lyse.

9.3 Fiber Type

9.3.1 DIFFERENTIATION

Under light microscopy using simple staining techniques, skeletal muscle appears to be a homogeneous tissue. However, muscle is composed of many fibers with differing characteristics. Myofibers may be grouped into two categories: type 1 and type 2. However, this classification is broad, and a spectrum of fibers has characteristics of both categories. The differences between fibers arise from variability in the proteins that comprise the contractile elements. Several different isoforms have been identified for the myosin heavy and light chains, tropomyosin, troponin-I, troponin-T and troponin-C. The greatest variability is in the isoform of the myosin heavy chain. Additionally, the calcium pumping capacity of the sarcoplasmic reticulum may vary from cell to cell.

All types of fibers are found in most skeletal muscles. Type 1 fibers are high in oxidative capacity and therefore rely on glucose, free fatty acids, and a high amount of oxygen to supply energy for contraction. Their sarcoplasmic reticula have a moderately slow reuptake of calcium capacity. Therefore, type 1 fibers are best suited to moderate contraction speeds and sustained contractions over long periods of time. As one would expect, these fibers predominate in muscles involved in posture. Type 2 fibers have a fast myosin ATPase rate and a rapid capacity to reuptake calcium into the sarcoplasmic reticulum. They are larger diameter fibers compared with type 1 fibersand have a high glycolytic capacity, making them suited to powerful, faster contractions. These fibers predominate in the larger skeletal muscles of the body involved in locomotion and rapid fine motor movements such as around the eye. Type 2 fibers that have activities closer to type 1 fibers are called type 2A,

whereas those that exhibit vast and high anaerobic capacity are characterized as type 2B. Because of the high oxidative capacity oftype 1 fibers, these muscles often appear to have a deeper red color than fibers high in type 2A and 2B fibers.

Histologically, differentiation of muscle fiber types relies on the measurement of myofibrillar ATPase activity (the enzyme responsible for the breakdown of ATP at the actin-myosin cross-bridges). Staining for this enzyme distinguishes two distinct fiber types at pH 9.4. The slow-twitch type 1 fibers have a low activity at this pH and so appear lighter in color than the fast-twitch type 2 fibers. The type 2 fibers can be divided further by preincubation at a more acidic pH into types 2A, 2B, and even 2C (the pH values required for this differentiation vary with the laboratory but are around 4.5 and 4.3). Work is currently in progress at various centers to develop and refine antibody techniques for the identification of fiber types. These techniques may clarify some of the issues concerning fiber types in the horse, may overcomemany of the practical difficulties of myosin ATPase staining, and may be adaptable to automatic tissue analysis systems. 464 465

The metabolic properties of the myofibers also can be used to differentiate the fiber types. Most commonly they are divided into those with a low oxidative ability, that is, having a high concentration of the sarcoplasmic enzyme glycogen phosphorylase, or a high oxidative ability with high concentrations of the mitochondrial enzymes such as succinic dehydrogenase.[9–11]

9.3.2 INNERVATION

Two types of motor nerve fiber are found. Each motor neuron may innervate a few or several hundred myofibers. Each myofiber, however, is only innervated by a branch of one motor neuron. The type of motor neuron determines the physiologic and biochemical nature and thus the type of myofiber. The large phasic motor nerve fibers innervate the type 2 myofibers, whereas the small tonic fibers innervate the type 1 fibers.

Sensory axon endings contact the muscle spindles, which are a bundle of specialized muscle fibers that run parallel to nonsensory muscle fibers. Muscle spindle cells are important in telling the nervous system about the tone and length of the muscle. They are important in maintaining posture. Discharges are relayed directly to the ipsilateral spinal motor neurons that innervate the muscle in which the spindle is located, resulting in a reflex arc. Two types of sensory neurons innervate each spindle:the primary endings are from the large-diameter group 1A afferent axons, whereas the less elaborate secondary endings are from the smaller group 2 afferent axons. The spindle cell fibers also receive motor neuron innervation from small γ-motor neurons, which helps keep the spindle taut when the muscle contracts, which in turn enables the sensory endings to respond to a wide range of muscle lengths.

TABLE 9-1 Fiber Type Characteristics

	TYPE 1	TYPE 2* A	TYPE 2* B
PHYSIOLOGIC CHARACTERISTICS			
Speed of contraction/twitch	Slow	Fast	Fast
Fatigability	Low	Intermediate	Rapid
Maximum tension developed	Low	High	High
HISTOCHEMICAL PROPERTIES			
Myofibrillar ATPase stain pH 9.4	Light	Dark	Dark
Preincubation at a pH of			
≈4.5	Dark	Light	Medium
≈4.3	Dark	Light	Light
Oxidative capacity	High	Intermediate-high	Low
Enzymes for glucose breakdown	Intermediate	High	High
Enzymes for free fatty acid breakdown	High	Intermediate	Low
No. of capillaries	High	Intermediate	Low
Glycogen content	Low	High	High

* Type 2C fibers have been described following acid preincubation with staining intensities between the light type 2A and medium type 2B fibers.

Muscle spindle cells are different from the muscle Golgi tendon organ. A sensory nerve ending wraps around each Golgi tendon organ. These organs are found at the ends of the muscle fibers at the musculotendinous junction and are formed from a common tendon to which a number of muscle fibers are attached. The sensory nerve innervating the Golgi tendon organ responds to tension generated by the contraction of any of these muscle fibers and the discharge is relayed to the ipsilateral α-motor neurons, where it is inhibitory. This forms another reflex arc responding to muscle tension and helps ensure that muscles of flexion and extension do not contract simultaneously.

9.3.3 CHARACTERISTICS

Type 1 fibers tend to depend largely on aerobic metabolism of glucose and fatty acids for their energy. They are capable of prolonged activity but slower contraction responses. The type 2 fibers derive energy mainly from anaerobic glycolysis with glycogen as the main substrate. These fibers become fatigued more rapidly but are capable of rapid contraction and therefore are found in the highest proportions in muscle groups that move limbs rapidly. Table 9-1 gives a summary of the characteristics of the different fiber types.

465

9.3.4 FIBER RECRUITMENT

Under neural control an orderly selection of fibers occurs with increasing demands. When just maintaining posture or walking, the horse uses only the nerves supplying the slow-twitch type 1 and possibly a few of the intermediate type fast-twitch high-oxidative type 2A fibers. As the speed or intensity of work increases, more and more fibers are recruited. Thus at a medium trot, approximately 50% of the muscle cells within a muscle belly are contracting, whereas at the gallop, most or all fibers are involved. The fibers are recruited in a set order: type 1, type 2A, and then type 2B. The gradation in response of a muscle is known as the recruitment of motor units. A motor unit consists of a motor nerve and the cells it innervates. The smoothness of a muscular contraction occurs because of the asynchronous contraction of the various motor units.

9.3.5 DISTRIBUTION

The proportions of fiber types present within a muscle vary according to the muscle, the breed, and the age of the horse, as well as the horse itself.[10–18] In some muscles (in particular, the middle gluteal muscle, which is sampled most commonly) the distribution also depends on the sampling site or depth, because the distribution of fiber types is nonhomogeneous.[10,17,19,20] The suggestion has been made, however, that within a specific muscle of an individual, the variation in fiber types is small if samples are taken from the same site or an identical contralateral site under controlled conditions.[17,21]

The type 2C fibers are found in large numbers in young animals but are rare in the mature horse, in which they usually are referred to as transitional fibers. These fibers have been suggested to be a stage in the development of new fibers from satellite cells or fibers in direct transition from one fiber type to another.[19,22]

9.3.6 EFFECT OF TRAINING

The suggestion has been made that the relative proportions of type 1 and type 2 fibers are under genetic control and under normal training conditions cannot be altered significantly.[22,23] Changes in the relative proportions of type 2A and 2B fibers have been reported, however, although some controversy has arisen regarding this interconversion.[7,24,25] In general, the suggestion is that training results in (1) an increase in the ability of a fiber to use oxygen by increasing the number of mitochondria within the sarcoplasm, (2) a decrease in the use of muscle glycogen and blood glucose with a greater reliance onfat oxidation to supply ATP, and (3) a decrease in the amount of lactate produced per given intensity of exercise.

Variable results have been reported on the effects of exercise on fiber size and capillarization. The extent and nature of the changes appear to depend on the duration, intensity, and type of exercise involved, as well as theage of the animal. Further information on the effect of training on muscle is available.[7,19,23–30]

9.3.7 RELATIONSHIP TO PERFORMANCE

A relationship has been suggested to exist between performance and the proportion of type 1 and type 2 fibers and their subtypes.[22,24,31,32] Performance, however, depends on many factors, just one of which may be the genetic endowment of fiber type distribution, coupled with the beneficial effects of appropriate training. Given

the heterogeneity of muscle, basing any performance characterization solely on the relative proportions of the fibers is therefore likely to be misleading.[22,24]

9.4 Muscle Development and Growth

Mammalian skeletal muscle develops from the embryonic myotomes. Some myoblasts remain as single cells, retain their mitotic ability, and form regenerative satellite cells. Fusion of the remaining mononuclear myoblasts to form multinucleated myotubules is believed to be the waythat muscle fibers develop in the fetus. Smaller secondary myotubules then form on the surface of these large primary myotubules. Initially, these myotubules share a common basement membrane but soon become separate. The suggestion has been made that the primary myotubules develop slow-twitch (type 1) fiber characteristics, whereas the secondary myotubules develop fast-twitch (type 2) characteristics. Genetic, hormonal, and nutritional factors may influence the number of these primary and secondary myotubules.[33–36] Near to the time of birth and for a period afterward, a proportion of the secondary fibers that lie closest to the primary fibers may become modified to form type I fibers,[37] although by this stage, innervation of the fibers with their specific nerve types already should have occurred. Therefore the suggestion has been made that an "unplugging" from one neural type to another can occur during development in response to motor stimulation. However, much confusion still exists regarding fiber differentiation.[33,38]

Tertiary and later generations of myotubules form between the first- and second-degree myotubules. Formation is accompanied by concurrent maturation of the established myotubules to myofibers, including migration of the nuclei to a peripheral position and synthesis of contractile proteins. Established fibers then increase in diameter and length. This process is associated with the fusion of mononuclear satellite cells with the fibers. Postnatal increases in fiber diameter are associated with the addition of myofilaments and an increase in the number of myofibrils (perhaps derived from the satellite cells). Increases in length occur by the formation of extra sarcomeres together 466
with a slight increase in mean sarcomere length. In the horse, training has been suggested to cause an increase in 467
the absolute number of fibers,[26,29] but this is disputed because the number of cells in most muscles is believed to be established earlyin life.[7,24] Other work has supported the idea that the increase in muscle volume, associated with growth and training, does not depend on an increase in the number of fibers but on the hypertrophy of each muscle fiber.[39]

9.5 Pathologic Changes

9.5.1 GENERAL RESPONSE OF MUSCLE TO INJURY

Muscle responds to injury or damage in a limited number of ways. A growing body of evidence indicates that all myopathic conditions share a common final pathway of muscle fiber degeneration,[40] although the number and type of fibers affected and the degree of damage varies. The final common pathway involves failure to sequester calcium ions from the sarcoplasm. Prolonged calcium accumulation within the sarcoplasm leads to activation of cellular enzymes and prolonged activation of myofilaments. This process is visible histologically as hypercontraction. Consequently, mitochondria take up excess calcium in an attempt to prevent cellular damage. Accumulation of calcium within the mitochondria leads to failure of energy production (ATP) within the cell and eventually failure of all intracellular energy-dependent mechanisms, which leads to failure of membrane pumps and ultimately cellular swelling and lysis.[40,41]

The exact nature of these calcium-activated degenerative pathways is still unknown. A recent suggestion is that a key step may be calcium-induced membrane phospholipid hydrolysis via the activation of phospholipase enzymes, resulting in the production of tissue-damaging metabolites. Other processes, however, involving nonenzymatic lipid peroxidation also may be activated. During exercise, the flow of oxygen increases. At the same time, an overall depletion of ATP sources occurs. The resultant metabolic stress to the cells leads in turn to a greatly increased rate of oxygen free radical production that may exceed the scavenger and antioxidant defense systems of the cell, leading to a loss of cell viability and damage. This process could initiate skeletal muscle damage caused especially by exhaustive exercise. Possibly the increase in free radical activity can lead to a failure of calcium homeostasis and consequent muscular damage, or alternatively, calcium overloading may lead to an activation of free radical–mediated processes.[42] Multiple initiators likely may lead to this final common pathway depending on the type of exercise, fitness level, presence or absence of underlying genetic defects in muscle metabolism, and nutritional status of the horse. Free radical–induced skeletal muscle damage may be especially important if reperfusion follows a period of ischemia.[43]

Because muscle responds to stressors similarly, recognizing that muscle disorders only rarely can be diagnosed on the basis of muscle histopathology alone is important. A thorough history including genetic, exercise, nutrition, patient signalment, and clinical description of the muscular disorder is mandatory. This information—along with histologic evidence of the distribution, character, and age of the lesions; the presence or absence of certain cell types and parasites; and lesions in other organs—in most cases provides the practitioner with enough evidence to make a diagnosis.

Histochemical staining of frozen muscle sections also can aid the detection of glycolytic enzyme deficiencies and indicate the storage of various atypical metabolic compounds.[44–47] For example, phosphorylase deficiency has been described in human beings (McArdle's disease) and Charolais cattle.[48,49] The nature of any cellular infiltrate also may be of interest, for example, in trichinosis, in which an eosinophilic and neutrophilic infiltration of any necrotic sarcoplasm may be present. In most cases of segmental necrosis only a limited secondary involvement of the interstitial tissues or blood vessels occurs. With vascular injury and regional necrosis (following arterial or venous occlusion, hemorrhage, or trauma), the necrosis of the muscle fibers is only part of a more extensive lesion involving the interstitial tissue and blood vessels.

Other, more general pathologic changes that can be found in muscle include changes in fiber volume, number, shape, malformation, degeneration or proliferation of organelles, and disruption of the basic architecture of the fiber. Aggregates of inflammatory cells, reactive changes in vessel walls, occlusion of blood vessels, and increased amounts of fibrous tissue are other possible pathologic findings. In some conditions, such as tetanus or botulism, however, no significant changes have been identified in the muscles themselves. Further information on the types of changes that occur is available.[37,44,50]

Various histologic stains have been developed to highlight the different morphologic changes and inclusions that occur.[11,44,51,52] The most important of these is the periodic acid–Schiff stain that highlights glycogenstores within a cell and membrane structures containing mucopolysaccharide, glycoproteins, mucoproteins, glycolipids, or phospholipids. Large aggregates of abnormal polysaccharide occur in Quarter Horses with polysaccharide storage myopathy and Draft-breed horses with equine polysaccharide storage myopathy. Histochemical staining for fiber type enables the pathologic changes to be recognized as affecting all fibers or those of one type only. In cases of reinnervation, large groups of a single fiber type are visible as opposed to the more interspersed pattern typically observed.

These procedures can be combined with a morphometric examination of the muscle[4] to provide further 467
information. Immunocytochemical studies have been used in the investigation of neuromuscular disorders in 468
human beings and to diagnose autoimmune streptococcal-associated myositis in the horse.[44] Specialized staining techniques help to localize specific enzymes and intracellular and extracellular muscle components such as the various collagen and myosin types, complement, and fibronectin. Electron microscopic studies enable one to investigate the ultrastructural reactions of muscle fibers. To date, these advanced techniques have been applied sparingly in the horse; however, their use is a developing field in human and veterinary medicine.[34]

9.5.2 ATROPHY AND HYPERTROPHY

Atrophy may be defined as a decrease in muscle fiber diameter or cross-sectional area. Atrophy can occur in a variety of circumstances, including denervation, disuse, and cachexia, and in many muscle diseases, following circulatory disturbances, and extensive myolysis. Within 2 or 3 weeks following peripheral denervation, up to two thirds of the originally supplied muscle mass may be lost, although this may not always be obvious clinically because of the continued presence of superficial and intramuscular fat deposits. The changes seen histologically reflect the affected nerve and the muscle fiber type it supplied. In disuse, atrophy resulting from tenotomy—for example, a preferential atrophy of type I fibers—is apparent, often with hypertrophy of type II fibers. In contrast, with cachexia and malnutrition, generally the type II fibersare affected, especially in the essentially postural muscles. Not all muscles show the same degree of atrophy, even within one disease process. In cachexia, the back and thigh muscles tend to be the first affected, and the loss of muscle is usually symmetric, with a concurrent loss of fat deposits. A localized asymmetric atrophy is associated with paralysis, immobilization, and denervation.[37]

As indicated previously, hypertrophy may occur through training. A compensatory hypertrophy also may occur in the fibers surrounding an area where fibers have been lost or have decreased greatly in size; for example, with chronic denervation atrophies and in advanced cachectic atrophy. Often, large fibers are visible histologically in such conditions, with evidence of incomplete longitudinal division.[37]

9.5.3 REPAIR AFTER DENERVATION AND INJURY

9.5.3.1 Following Denervation

Reinnervation can occur in two ways. Damage to a nerve without severing the nerve is called axonotmesis. The axon is damaged but the Schwann cell and endoneural fibrous sheaths remain. Axons from the proximal partof the damaged nerve may reestablish connections with empty residual Schwann cell sheaths in the distal portion of the original nerve. Initially, atrophy of scattered muscle fibers is visible, but after reinnervation, if this occurs within a certain time, a proportion of the muscle fibers are restored to their normal size and functional capability. Even if the affected muscle is not restored fully, other surrounding unaffected muscles may be able to compensate so that overall function is maintained. A slight gait abnormality may remain, however.

The second type of reinnervation tends to occur when some nerve fascicles are severed completely or when the lesion is located a great distance from the muscle; for example, when lesions have involved the motor neuron cell bodies and nerve roots. In these circumstances, collateral reinnervation from adjacent, unaffected axons can occur. As the nerve type characterizes the muscle type, this results in regrouping of muscle fibers so

that with successive episodes of denervation and reinnervation, clusters of fibers of the same histochemical type are found rather than the normal checkerboard pattern. This effect is referred to as *fiber type grouping*.

9.5.3.2 Following Injury

Regeneration where a break in the continuity of the muscle fiber has occurred differs considerably from that involving primarily neurologic damage. In such cases repair involves multiplication of nuclei and formation of new internal structures and organelles followed by fusion and alignment into a new multinuclear myofiber. Regeneration seems to take place only if parts of the affected fiber remain intact. If this is so, recovery can be quick. Regeneration can occur at the healthy end of the severed fiber (continuous or budding regeneration) or by fusion of mononuclear myoblasts to form a myotube, which develops in a similar way to fetal fibers (discontinuous or embryonic regeneration). The origin of myoblasts is disputed. Some workers believe they are derived from undamaged sarcoplasmic nuclei, others think that they come from satellite cells.[52] If the scaffolding, basement membrane, and supporting tissues remain intact, and the initiating disease process subsides, new fibers tend to orient in a way similar to the original fibers. This type of regeneration usually occurs with segmental necrosis, in which necrosis of the whole diameter of the fiber has occurred, often involving several sarcomeres, but the basement membrane has been preserved. Fibroblastic and vascular reactions are minimal in this type of regeneration. Therefore full function of the muscle is restored without residual dysfunction.

Massive trauma, hemorrhage, infection, or infarction can result in damage to the basement membrane and other supportive structures, resulting in complete disorientation of the regenerating fibers with significant proliferation of fibroblasts and vessels. In such cases, after regeneration significant deformation of the muscle may occur with potential disruption of its normal function. 468

469

9.6 Diagnosis of Skeletal Muscle Disorders

The clinical signs of muscle disorders are few and nonspecific. In acute muscle injury, clinical signs may include “knots” or regions of varying size of hypercontracted fibers within the muscle or areas of edema with or without heat within the muscle, pain on palpation, fatigue with light exercise or reluctance to move, atrophy, occasionally weakness, and discolored urine (myoglobinuria). In cases of infectious myositis such as clostridial infections, one may palpate gas accumulation evidenced by crepitus.

In cases of chronic muscle disease such as fibrotic myopathy, one may palpate firm areas of fibrosis or calcification with limited pain and heat. Gait abnormalities in cases of chronic muscle disease most commonly are associated with denervation atrophy and fibrotic myopathy. The practitioner may perform ancillary diagnostic testing to characterize the significance of the disorder further and to aid in diagnosis. These tests can include histologic and histochemical examinations of the muscle, thermography, electromyography (EMG), and most commonly in equine medicine, plasma-serum biochemical investigations for creatine kinase (CK) and aspartate aminotransferase (AST).

9.6.1 MUSCLE BIOPSY

The practitioner can obtain muscle biopsy samples by surgical excision under general or local anesthesia[53] or more commonly by percutaneous needle biopsy from the standing horse.[9,13,54] Because of the variation in fiber composition with sample site in certain muscles, the position and depth of sampling are important. Good specimen preparation for frozen sections is vital to prevent artifacts such as ice crystals, sarcomere shortening,

and fiber kinking.[9,44,55] For laboratories that prefer examination of frozen sections, specimens typically are shipped chilled so that the laboratory may freeze the sample themselves to minimize artifacts. Other laboratories prefer formalin-fixed specimens. The practitioner should discuss sample procurement, preparation, and shipment procedures with the laboratory before biopsy.

Muscle biopsy allows the morphologic, biochemical, and physiologic properties of the myofibers to be examined with the animal still alive and with minimal complications, especially if obtained by percutaneous needle biopsy, for which chemical sedation rarely is required. Typical sites used for percutaneous biopsy in cases of generalized muscle disease include the semimembranosus, the biceps femoris, and most commonly the middle gluteal muscle. In horses in which a specific muscle is abnormal, the two methods described next can be adapted readily to that particular muscle.

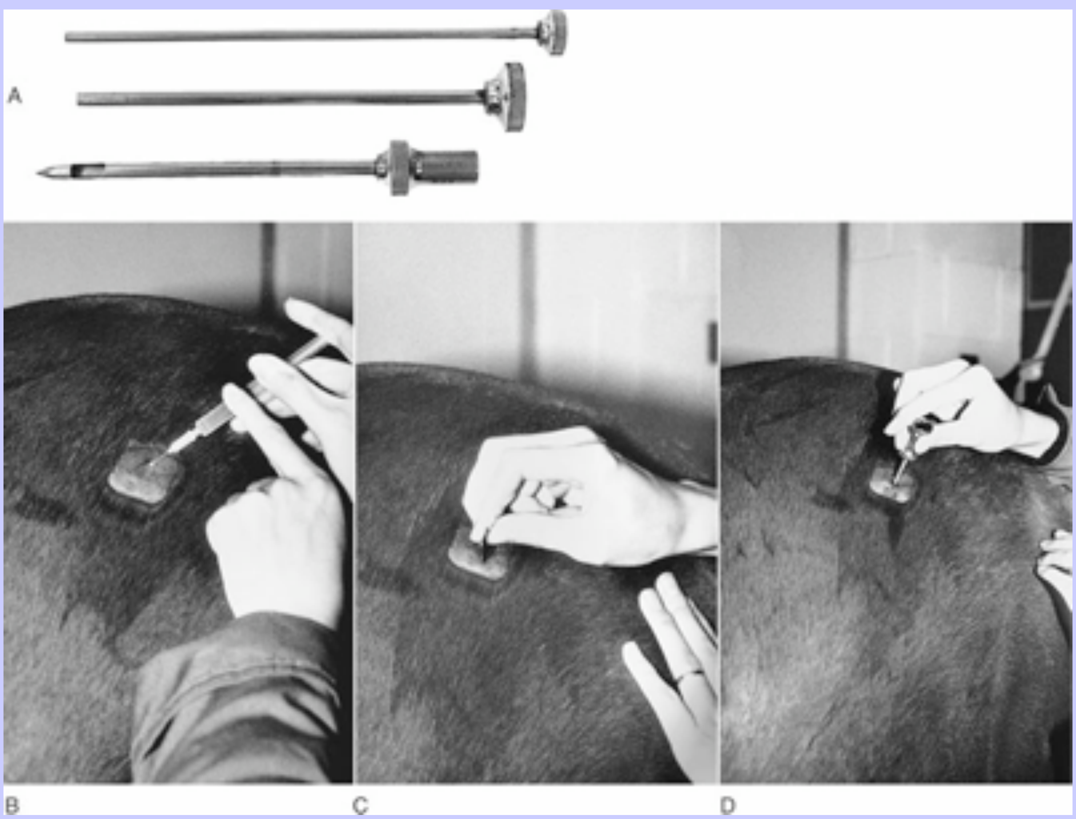
Figure 9-2 gives details on the procedure for obtaining a muscle biopsy from the middle gluteal muscle. The practitioner draws a line from the tuber coxae to the base of the tail. Approximately midway along this lineis the highest point of the middle gluteal muscle. At this point the practitioner closely shaves, washes, and cleans a small area of skin. The practitioner then injects local anesthetic subcutaneously along the proposed line of incision and into the connective tissue or fascia overlying the muscle but does not inject anesthetic into the muscle itself, which may induce artifact into the biopsy. The muscle belly is innervated poorly for pain, and therefore reaction to the insertion of the muscle biopsy needle is minimal. Horses react because with insertion of the needle the muscle spontaneously contracts. The practitioner then makes an incision through the skin and fascia and inserts a 4- to 6-mm biopsy needle to a predetermined depth. The practitioner catches and removes several small pieces of muscle with the needle and leaves the incision unsutured or uses a single skin suture to minimize bleeding and for client reassurance. Biopsies smaller than 4 mm typically do not provide enough muscle tissue for an adequate diagnosis, and for most horses6 mm is preferrable. This procedure rarely has complications; however, the horse should be current on tetanus prophylaxis as a general precaution. A scar from the incision rarely occurs.

When practitioners do not have muscle biopsy needles, they may take excisional biopsies from the semimembranosus muscle. The biopsy site is slightly lateral to and below the anus. At this location, if a scar occurs following the procedure, the tail will hide it. The practitioner surgically prepares the site and makes an inverted L lidocaine block of the skin and subcutaneous tissues. The practitioner then obtains a piece of muscle measuring approximately 1 × 1 × 2 cm and sutures closed the subcutaneous layer and skin. Buried skin sutures that do not need to be removed appear to be preferable because they are less likely to cause skin irritation and therefore are less likely to be rubbed out by the patient. Should the horse open the biopsy site, the wound typically heals well by second intention with general wound care.

9.6.2 THERMOGRAPHY

An infrared thermographic scanner converts the radiated thermal energy of the skin to electric signals that canbe amplified and displayed on a video screen. By using isotherm colors of known temperature, the practitioner can obtain two-dimensional, graphic, and quantitative information regarding the precise temperature of the skin surface. The practitioner can use this technique noninvasively as a means of detecting changes in skin temperature resulting primarily from changes in peripheral blood flow. Inflammation, atrophy, neoplasia, and neurologic lesions, particularly of the autonomic supply to the skin, can alter local blood flow. 469

Figure 9-2 **A**, Percutaneous muscle biopsy needle, often referred to as a Bergstrom biopsy or Stille-Eschmann cannula, available with 4-mm, 5-mm, and 6-mm internal diameters (6 mm is preferred). **B**, One closely shaves, cleans, and prepares a small area (approximately 2.5 cm) of skin over the gluteal muscle (two thirds of the distance on a line from the tail head to the tuber coxae) in a sterile manner and injects 1.5 ml of local anesthetic (lidocaine 2% with epinephrine) subcutaneously along the proposed line of incision and into the connective tissue or fascia overlying the muscle. One does not inject anesthetic into the muscle tissue.**C**, One makes an incision through the skin and fascia using a No. 23 scalpel blade. **D**, One inserts the biopsy needle into the muscle to a predetermined depth (indicated by an indelible mark on the shaft of the biopsy needle). Using the Tru-Cut principle, one can catch and remove with the needle a small piece of muscle (up to 100 mg). The incision is left unsutured.



Abnormalities have been found in exercise-exacerbated focal thoracolumbar gait abnormalities, as well as disuse atrophy.[56] The technique has been particularly usefulin documenting hindlimb muscle strain as a cause of lameness in horses.

9.6.3 ELECTROMYOGRAPHY

Needle EMG is the study of the electric activity of muscles. The practitioner places a recording needle electrode into the muscle, and the electric activity is amplified, recorded on an oscilloscope, and projected audibly into a loudspeaker. The electric status of muscle membranes depends on the integrity of the wholemotor unit. Thus an EMG evaluates the function of the ventral motor horn cell, its axon, axon terminals, and neuromuscular junctions, as well as the muscle fibers it innervates.

Investigations usually are carried out in two phases. First, the practitioner assesses the electric potentials 470
associated with physical disruption of muscle membranes resulting from insertion of the needle in the muscle. 471
These insertional potentials, if relayed through a loudspeaker, tend to sound like short bursts of loud static. They vary among muscles, probably because of differences in the size and number of motor units present.

The second phase involves assessment of electric potentials when the needle electrode is at rest in the muscle. Normally, electric silence occurs with cessation of needle movement, unless the needle is located in proximity to a nerve branch or the end plate zone when miniature end plate potentials are recorded continuously; these sound like a low-intensity static. In cases of denervation, insertional activity may persist after needle movement has stopped because of increased excitability of the muscle fiber membranes. In relaxed, diseased muscles, different types of abnormal electric activity have been recognized. Positive, sharp waves are slow monophasic waves, rapid in onset, with a slow decay to the baseline, which occur repeatedly with variable amplitude (100 μV to 20 mV). Their cause is uncertain, and they often occur with denervation and may represent a nonpropagated depolarization region in the muscle fibers near to the tip of the electrode. When occurring in trains, these positive sharp waves sound like a waning *brrrr*.

Fibrillation potentials are electric signals generated by a single muscle fiber. Long, random volleys of mono- or biphasic (occasionally triphasic) potentials of short duration (0.5 to 5.0 ms), with amplitudes of usually less than 200 μV, commonly occur in denervation (depending on the stage). Constant and repetitive fibrillation potentials, which sound like rain on a tin roof or the sizzling of frying eggs, can be found especially in the early stages of denervation. Fibrillation potentials also can be seen in myopathic disorders in which segmental muscle necrosis may have caused, for example, the separation of a muscle fiber and its nerve supply.

Myotonic discharges—high-frequency (up to 1000 Hz) repetitive discharges with a waxing and waning of the potentials seen and heard with a characteristic, musical, dive-bomber, or more precisely, revving motorcycle–like sound—are found in the myotonias (myotonia congenita, myotonia dystrophica, and hyperkalemic periodic paralysis) if the practitioner moves the exploring EMG electrode or percusses the muscle externally. Bizarre, high-frequency discharges (often referred to as pseudomyotonia) may produce a dive-bomber–like sound. No true waxing and waning occurs, although the amplitude and frequency of the potentials may change abruptly to mimic a revving motorcycle–like sound. The discharges are often in couplets or triplets and are likely to terminate abruptly. These, or similar discharges, occur in long-standing denervations, ventral horn cell disease, polymyositis, and certain myopathies. Unlike the myotonic discharges, pseudomyotonic discharges may be abolished by curare and therefore are believed to originate presynaptically.

Fasciculations, often seen in association with visible muscle twitching, are caused by the spontaneous contraction of some or all of the constituent fibers of a motor unit. They occur primarily with any cause of muscular weakness (myasthenia), local or generalized, especially in neurogenic disorders, and in tetanus and certain debilitating and metabolic disorders. In addition, one can assess the electric activity induced by electric stimulation of nerves or associated with voluntary or induced muscle contraction.

Further information on EMG is available in the literature.[57–60]

9.6.4 SCINTIGRAPHY

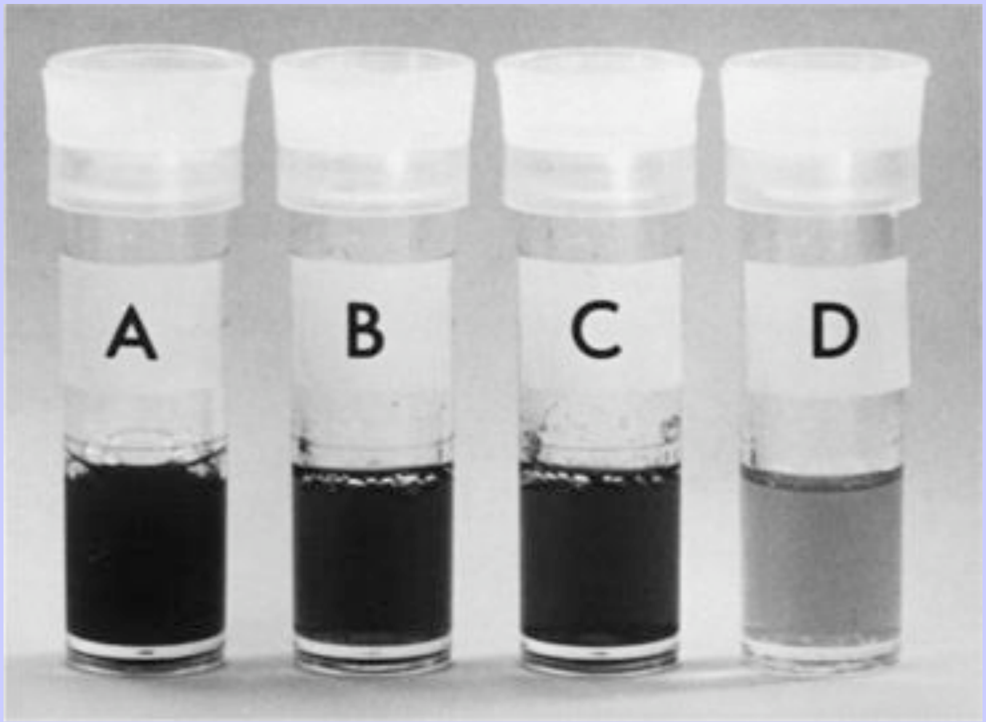
Bone-seeking radiopharmaceuticals have been used to detect and localize skeletal muscle involvement, especially in poor performance cases, but are likely to be of limited routine value in the field. The accumulation in damaged muscle may be related to the deposition of calcium in damaged fibers, binding by tissue hormones or enzyme receptors, tagging to denatured proteins, or altered capillary permeability. Uptake of labeled phosphates appears to occur only when muscle damage is ongoing and does not occur in areas of repair. Three main types of muscle uptake were identified in one study of horses with skeletal muscle damage: a diffuse, severe, and generalized uptake; bilateral symmetric uptake involving muscle groups that perform synergistic functions; and asymmetric radioisotope uptake in one or more muscle groups on one side of the animal.[61] The reasons for the various patterns have not been elucidated fully.

9.6.5 URINALYSIS: MYOGLOBINURIA

Myoglobin (molecular weight 16,500) is essential for the transport of oxygen into and within muscle cells. Most mammalian muscles contain about 1 mg myoglobin per gram of fresh tissue, and the suggestion has been made that acute destruction of at least 200 g of muscle must occur before serum myoglobin levels rise sufficiently for detection in the urine.[62] Serum myoglobin has a short half-life, and therefore measuring serum myoglobin is of limited diagnostic value. In human beings, myoglobinuria occurs in a variety of conditions, including myocardial infarction, crush and burn injuries, malignant hyperthermia, idiopathic and exertional rhabdomyolysis, and certain genetic metabolic abnormalities.[50,51,62–64] In the horse, myoglobinuria has been seen, for example, in equine exercise-induced rhabdomyolysis,[65,66] white muscle disease in foals,[67] and postanesthetic myositis.[68]

Pigmenturia or dark urine may be caused by increased myoglobin, hemoglobin, or whole blood in the urine. Low 471
levels of myoglobin, hemoglobin, or whole blood may occur in the urine and can be detected by urine dipstick or 472
laboratory test before visible changes in the color of urine. Therefore considerable amounts of myoglobin, hemoglobin, or whole blood must be present for visible pigmenturia to occur. Many causes of hemolysis in the horse can result in hemoglobinuria, including acorn poisoning[69] and hepatic and renal disease.[70]

Figure 9-3 Four urine samples. *A*, With 3 mg/ml hemoglobin. *B*, With 3 mg/ml myoglobin. *C*, Normal stored for 1 month at 18° *C*. *D*, Control (fresh urine).



Unfortunately, stored urine, concentrated urine, and urine containing myoglobin, hemoglobin, or other porphyrins can appear similar in color[69,71,72] (Figure 9-3). Therefore one cannot distinguish myoglobinuria by color alone and must use other methods. The orthotoluidine-impregnated strips commonly used by veterinary surgeons (urine dipstick tests such as BM-Test-8, Boehringer Ingelheim Pharmaceuticals, Ridgefield, Connecticut) are insensitive to the presence of myoglobin and hemoglobin.[66,73] The differential salting out of hemoglobin with ammonium sulfate has been shown to give false resultsin human beings[62,63,71,74] and the horse but is used commonly in many laboratories.[73] Visual inspection of the serum or plasma may indicate the cause of the pigmenturia. The low affinity of myoglobin for haptoglobin means that myoglobin is excreted at plasma concentrations around 0.2 g/L, whereas hemoglobin only appears in the urine at plasma concentrations greater than 1.0 g/L. At this concentration a pink discoloration of the plasma occurs, indicating that hemoglobin is present.[53,62,63]

Spectroscopy has been used to differentiate between the oxyforms of myoglobin and hemoglobin but does not identify oxymyoglobin when oxyhemoglobin isalso present. In fresh urine, oxymyoglobin is converted rapidly to its met-form, and in older urine samples both oxyforms will have been converted spontaneously to their met-forms. These oxyforms can be reduced chemically, but this can result in a denaturation of the proteins. In human beings, because methemoglobin and metmyoglobin have almost identical absorption spectra, spectrophotometry has been stated not to be able to distinguish one from the other if both are present in the sample.[74] The same has

been shown for the horse. Ultrafiltration also has been shown to be unreliable in the horse, perhaps because of the higher viscosity of equine urine compared with human urine.[73]

On electrophoretic separation on cellulose acetate, myoglobin migrates as a β_2-globulin and hemoglobinas an α_2-globulin. This method can distinguish the two proteins in urine containing high concentrations(>125 μg/ml) of either protein, provided no other proteins, apart from albumin, are present. Immunoassays are the most sensitive and specific tests and can be used for detecting small amounts of myoglobin in blood and urine.[73,75,76] Sequelae of acute tubular necrosis and acute renal failure have been associated with myoglobinuria in human beings[77] and horses.[53,78] Renal disease associated with myoglobinemia in the horse seems to be associated most with horses that are highly stressed (causing decreased renal blood flow), dehydrated, and have lactic acidosis associated with rhabdomyolysis. Therefore horses suffering from “capture” myopathy (e.g., cast in a stall or trailer accident and struggling for a prolonged period of time) and endurance horses are most at risk.

9.6.6 PLASMA AND SERUM ENZYME ACTIVITIES

The enzymes found to be most useful in evaluating the equine muscular system are CK, AST, and lactate dehydrogenase (LDH). A change in the plasma activity ofany enzyme can occur for a variety of reasons, including alteration in the permeability of the enclosing cell membrane, cell necrosis, impaired removal or clearance of the enzyme, and increased or impaired synthesis. Decreases in plasma enzyme activities are not usually clinically significant. Often no one specific organ of elimination is responsible, although most elimination occurs via the liver, kidneys, and lungs. Therefore under most circumstances the elimination rate of an enzyme from the plasma remains fairly constant, and the rate of influx to the plasma is the crucial factor.

Increases most commonly occur because of a defect in the integrity of the membrane containing the enzyme.[79,80] The defect results from complete disruption of the cell or a transient change in the permeability of the membrane without cell death. A complete explanation forthe pattern of release of intracellular constituents from diseased muscles cannot be given here. Most of the enzymes that are detectable in increased concentrations in the blood
with the various muscle disorders are the major soluble (sarcoplasmic) enzymes, although one also can find the 472
mitochondrial form of AST with severe injury. Intensification of cell function, as would occur during exercise or 473
as a reaction to cell damage, resultsin increased substrate use, which in turn may result in greater membrane permeability. Whether the increase in substrate permeation of the boundary surfaces themselves is sufficient to allow incidental escape of cell enzymes or whether a reduction in the energy potential is needed before cells leak is not clear. Therefore assuming a particular degree of cell death or damage from moderately elevated serum enzyme activity is inappropriate.

The suggestion has been made that considerable enzyme efflux can occur even when the light and electron microscope cannot detect with any certainty changesin cell structure. In the human disease Duchenne's muscular dystrophy, for example, the suggestion is that a change occurs in the structure of the sarcolemma at the molecular level that leads to a selective passage of cellular constituents based partly on molecular weight.[80] Under general circumstances the rate of efflux of an enzyme most likely depends not only on molecular weight and intracellular localization but also on its binding to various intracellular structures and its relative intracellular and extracellular concentration. No explanation for the significant differences in half-lives of the various plasma muscle enzymes reported for human beings and horses has been given.

9.6.6.1 Creatine Kinase

CK is the enzyme responsible for breaking down creatine phosphate to creatine and phosphate, releasing energy for muscular contraction. This reaction is the sole source of energy in muscle at the initiation of exercise. Thereafter, energy is supplied by oxidation of glucose and free fatty acids. Because this enzyme is responsible for the breakdown of creatine phosphate, it often is referred to mistakenly as creatine phosphokinase. This term is inappropriate, and one should use *creatine kinase*. In the horse, CK is found mainly in skeletal muscle, the myocardium, and the brain.[81] Little or no exchange of CK between the cerebrospinal fluid and plasma appears to occur. A significant increase in total plasma CK activity thereforeis caused by cardiac or skeletal muscle damage. CK (80,000 d) does not enter the blood stream directly after its release from the muscle cell but transits through the lymph via the interstitial fluid. The total quantity of circulating CK in the horse is estimated to be equivalentto the quantity of CK in approximately 1 g of muscle;a three- to fivefold increase in plasma CK activity corresponds to the apparent myolysis of approximately 20 g of muscle.[82] However, as described previously, making assumptions as to the amount of muscle damaged on the basis of serum CK activity is difficult, because muscle cells appear to be able to release significant quantities of CK without necessarily being lysed.

In human beings, two monomers of CK are known and are designated M and B. The enzyme is dimeric and three possible primary forms exist: MM, MB, and BB.In simplified terms, MM is found mainly in skeletal muscle, BB in the brain and epithelial tissues, and MB in the myocardium. In human beings the measurement of MB activities has been used as a sensitive test for the diagnosis of myocardial infarction.[83] Chronic skeletal muscle damage, however, has been suggested also to result in the characteristic myocardial infarction pattern.[84]

In the horse some confusion over CK isoenzymes exists with workers reporting different electrophoretic bands and tissue activities, perhaps because of the different techniques used.[85–88] In one study, the heart and skeletal muscle were found to contain predominantly the MM dimer; the brain, pancreas, and kidney, mainly the BB dimer; and the intestine, the MB and BB dimers.[87] This work suggests therefore that in the horse, CK isoenzymes on their own could not be used to differentiate between skeletal and cardiac muscle damage. This problem is alleviated largely by the current availability of tests for cardiac troponin I. Unfortunately, commercial tests for skeletal troponin I are not available. In the absence of clinical cardiac disease, one can attribute elevations in CK primarily to skeletal muscle. The plasma half-life of CK in the horse is short (108 minutes,[89, 123] ± 28 min with a plasma clearance of 0.36 ± 0.1 ml/kg/min)[82] in contrast to reports of 12 hours in human beings.[90]

9.6.6.2 Aspartate Aminotransferase

AST is found mainly in skeletal muscle, liver, and heart, although lower activities are present in several other tissues. Therefore AST is not tissue-specific.[78,81,91] Two isoenzymes have been identified by electrophoresis: MAST (found exclusively in the mitochondria) and CAST (originating from the cytoplasm or sarcoplasm). The ratio of cytosolic to mitochondrial enzyme in horse serum is significantly greater than that found in human beings and many other mammals.[92] In the horse, although the ratio of these two forms varies between tissues, no tissue-specificity is apparent for either isoenzyme. Therefore the conclusion is that the examination of sera for AST isoenzyme activities cannot indicate the tissue source, although large increases in MAST are unlikely to be found in the serum unless severe muscular injury has occurred. Some workers have reported an

apparently unique form of the enzyme in the sera from azoturia cases.[93] The plasma half-life of AST in the horse is 7 to 10 days,[89] far longer than the 11.8 hours in human beings.[90]

9.6.6.3 Lactate Dehydrogenase

LDH is a tetrapeptide made up of combinations of two different peptides, H (heart) and M (muscle), which form the five isoenzymes referred to as LDH_1 to LDH_5, that is, H_4, MH_3, M_2H_2, M_3H, and M_4, respectively. Like AST, LDH is found in most tissues and is therefore not organ-specific. However, tissues contain various amounts of the LDH isoenzymes, and the isoenzyme profile obtained by electrophoretic separation has been used to identify specific tissue damage.[94] For the most part, LDH_5 (plus some LDH_4) is found in the locomotor muscles; the liver contains mainly LDH_3 (with some LDH_4 and LDH_5); the heart contains mainly LDH_1 (with LDH_2 and LDH_3); and all types have been found in certain nonlocomotor muscles.[85,88] Training has been shown to increase the percentage of LDH_1 to LDH_4 and decrease that of LDH_5 in skeletal muscle.[95] The practitioner should use nonhemolyzed samples for LDH determinations because red blood cells contain large amounts of LDH.

473
474

9.6.7 EXERCISE TESTS

Certain physiologic changes can result in a transient alteration in cell membrane permeability. Hypoxia, catecholamines, hypoglycemia, changes in pH, and altered ionic concentrations have been reported as causing such a change in membrane permeability.[91,96,97] Many of these changes are believed to act by decreasing the amount of ATP available for the maintenance of cell integrity, which becomes especially important during exercise.[98]

Measuring the CK and AST activities before and after a controlled period of exercise has been suggested as an aid to diagnosing certain muscle disorders. A major difficulty has been to establish exactly the normal enzyme response to exercise. Much confusion exists in the literature regarding this partly because of the differences inthe intensity and duration of the exercise undertaken, the varying sampling intervals used in the reports, and the inclusion of individuals with possible muscular problems. The majority of workers have suggested that an increase in CK activities occurs with hard exercise,[98–100] whereas with slower work, others have shown no significant increase. This difference suggests that intensity could be an important factor.[101,102] Such a conclusion is supported by work in dogs, which shows that CK activities correlate with the intensity of muscular activity.[100] Another study in the horse,[103] however, suggested that CK elevations did not vary according to the intensity of the work, and one researcher[104] proposed that the duration of exercise was a more important factor. A recent study suggested that when the duration of exercise was kept constant, the intensity of the exercise in fact did have an effect on the extent of CK activity increase.[105] However, this investigation did not look at the effects of exercise duration on the CK response.

Although no significant increase in CK activity was found following trotting exercise in conditioned animals by one worker, others recorded significant increases when horses performed the same exercise after 1 or more days of rest.[101] Increases in AST activities of 35% have been reported following a 1500-m canter[107] and of 50% following strenuous exercise in previously rested animals.[99] Most other workers have found little increase in AST following different types of exercise.[89,92,104,108]

Therefore the effects of exercise on plasma muscle enzyme activities may depend on the fitness of the animal and the intensity and duration of the exercise, as well as on the environment.[85,104,109] In horses, as in human beings, large intersubject variability may occur in the postexercise rise in CK activities that must be taken into account.[82] Plasma volume changes may affect the activities recorded, especially if measured immediately after exercise. A test that would enable fit and unfit horses to be tested equally has been proposed and involves riding the horse over a given distance at a speed that produces a steady heart rate of 200 beats per minute.[110] However, exercising the horse at an exact heart rate is difficult, and many veterinary surgeons do not have access to heart rate monitors. This means that veterinary surgeons tend to use the same exercise test in all animals, regardless of their fitness.

As discussed previously, the physiologic increase in CK activity following exercise is believed to be caused by a change in cell membrane permeability, possibly caused by hypoxia, although other factors likely are involved. Hypoxia may occur at lower workloads in unconditioned horses, and these may be expected to show higher postexercise activities than a fit horse given the same work. The suggestion has been made that the magnitude ofthe exercise-induced rise in enzymes decreases with training.[89,103,104] Some workers have found no significant changes in the AST and CK responses to exercise during a training program,[102] whereas others have found that following an endurance ride, the fittest animals (indicated by speed of the heart rate recovery following an endurance ride) had lower increases in CK activities.[108] The magnitude of exercise-induced changes in CK activities has been shown to increase with detraining. This study concluded that increases of more than 100% in AST activity following exercise likely are abnormal, regardless of the intensity of the exercise or the fitness of the animal. Also, if a short, submaximal exercise test is carried out, the serum CK and AST activities at 2 hours after exercise should not rise to more than 250% and 50% of the preexercise values, respectively, regardless of fitness.[105]

The point has been stressed that although exercise might result in statistically significant changes in CK and AST activity, these may not always be of biologic or clinical significance.[111,112] The practitioner always must take into consideration the clinical history and clinical presentation, for example, when interpreting enzyme values. 474
For example, a young racehorse given its first gallop often has activity changes greater than those described 475
(e.g., from a preexercise level of 40 U/L to a 2-hour postexercise level of 350 U/L), although this is unlikely to be clinically significant. However, in cases of recurrent exertional rhabdomyolysis (RER) or polysaccharide storage myopathy (PSSM), similar changes may indicate ongoing subclinical muscular dysfunction. For example, in the author's experience, horses with RER or PSSM may have 4-hour postexercise serum CK activities of 10,000 to 15,000 U/L without outward clinical signs of rhabdomyolysis. In human beings, the suggestion has been made that no relationship exists between CK activity and the amount of muscle damage after an eccentric exercise bout, reflecting that CK activity is a manifestation of muscle damage rather than a direct indicator of its severity.[82]

Currently, the author recommends a submaximal exercise test, which varies for each horse. The practitioner should choose the intensity and duration of this test according to the fitness of the horse and the exercise program it is undertaking, with the aim of giving the horse strenuous exercise without overexerting it. Box 9-1 illustrates a normal response to such a test. Horses that recently have ridden in a trailer a long distance for evaluation may require 24 hours of hospitalization to ensure a normal CK value before the examination.

9.6.8 OTHER FACTORS AFFECTING AST AND CK ACTIVITIES

9.6.8.1 Gender and Age

A group of Thoroughbreds was sampled over a 9-month period, and the 2-year-old fillies showed more significant fluctuations in AST and CK activities than the 3-year-old fillies and colts. Unfortunately, no 2-year-old colts were studied.[113] In a later study of 66 2- and 3-year-old Thoroughbred racehorses in training, the fillies were found to be more likely to have high CK and AST activities than colts, and 2-year-olds were more likely to have increased AST activity than 3-year-olds. The effect of age on the incidence of increased muscle enzyme activities was thought not to have been caused by the natural loss of2-year-olds from training with high enzyme activities, especially because several of these raced and won.[114] Certain animals may have physiologically higher plasma activities, or their muscle enzymes may be removed more slowly from the circulation. Alternatively, they may be more sensitive to the various insults that cause permeability changes in muscle fiber membranes. Age or training or both could have a dampening effect on muscle membrane changes. In dogs a significant decrease in CK activities has been reported with age, but no difference was found between males and females.[115] In one study no correlation was found between plasma progesterone concentrations and the fluctuations in CK and AST activities.[113] However, a later study showed that when fillies with high median AST activities were removed from the study group, a highly significant relationship was found between progesterone and AST, but not CK activities, and estradiol showed a significant effect on CK but not on AST activities. In rats, CK release after exercise orin vitro electric stimulation is greater in males than in females. Estradiol has been suggested to have a protective effect and to attenuate CK influx.[116] However, further work on the role of such hormones in CK and AST activities in the horse is necessary before one can draw conclusions. In addition, one must examine all studies in large groups of horse with some scrutiny when one considers that the incidence of some underlying myopathies is high within a population. Considering that AST and CK tend to rise exponentially with muscle damage, a few outliers in a study may skew results significantly. The incidence of RER in Thoroughbred horses may be as high as 5% of the population,[117] which may account for some of the increases in CK and AST activities observed in the studies cited.

9.6.8.1.1 BOX 9-1 CRITERIA FOR A NORMAL RESPONSE TO A SUBMAXIMAL EXERCISE TEST DESIGNEDFOR A GIVEN HORSE[*]

1. Pre-exercise:

   CK activity <100 IU/L (laboratory resting reference range, 0-49 IU/L)

   AST activity <300 IU/L (laboratory resting reference range, 150-230 IU/L)

2. Not more than a doubling of the resting CK activity at 2-4 hours after exercise
3. Return to baseline CK activities at 24 hours after exercise
4. Not more than a 50% increase in AST activity

5. No clinical signs of stiffness

* *CK*, Creatine kinase; *AST*, aspartate aminotransferase.

9.6.8.2 Time of Year and Training

Several workers have suggested that AST plasma activities increase in the early stages of training and then decrease as training progresses.[118,119] Time of year does not have a significant effect on the number of animals with normal or with high AST and CK activities.[114] However, researchers observed an increase in mean activities peaking in April and May and followed by a decrease to a lowin September in a group of Thoroughbred racehorses in the Northern Hemisphere.[114] The high mean activities in April, May, and June 475
were accompanied by high standard deviations, which made definitive conclusions difficult. Researchers also 476
found such large standard deviationsin another study of Thoroughbreds in training.[120] On an individual basis, a change in AST activities does not always seem to occur with training.[121] Therefore, decreases or increases in the serum levels of AST activity are probably not good indicators of peak fitness or overtraining.[92]

In a study of AST activities in a small number of barren and pregnant Standardbred mares, researchers apparently found evidence for a diurnal rhythm, with the lowest activities occurring in the early morning (4 to 6 AM) and the highest activities at night (10 to 12 PM). The mean activities increased from September to November until March. A circannual cyclicity was found, but the pattern differed between the two groups. In barren mares the arcophase appeared to occur in the second half of January, whereas for pregnant animals it occurredin September (approximately month 5 of pregnancy). The error fields, however, were broad.[122]

9.6.8.3 Relationship to Performance

Elevated CK and AST activities have been suggested to decrease the chance of a horse winning.[123] However, a group of 500 Standardbred trotters with a recent history of equine rhabdomyolysis and increased plasma muscle enzyme activities had a significantly better racing record compared with a large group of apparently unaffected horses.[25] Another study found that 50% of the horses with high median AST activities raced and won at least once.[114] However, determining whether these horses would have given better performances or won in better classes if they had not had such increased muscle enzyme activities obviously is not possible.

9.7 Classification of Myopathies

Coordinated movement and resting muscle tone rely on the interaction between the central nervous system and the motor units with input from the Golgi tendon organs (responding to muscle tension) and the muscle spindle apparatus (monitoring muscle length). Lesions in the neurons and their end plates (neurogenic myopathies) or in the muscle fibers themselves (myogenic myopathies) can induce pathologic alterations in skeletal musculature. The term *primary myopathy* has been given to any disorder attributable to fundamental morphologic, biochemical, or electric changes occurring in the muscle fibers independent of the central or peripheral nervous system.[124] Differences in the histologic appearance of neurogenic and myopathic myopathies have been reported in human beings[46,52] and horses.[125]

Classification of primary myopathies regarding pathologic changes is difficult, if not impossible, only because skeletal muscle has limited ways to respond to a variety of insults. The most useful basis for classification therefore may be cause. However, a firm etiologic basis for many causes of rhabdomyolysis in the horse has yet to be described. Therefore various systems have been suggested for the horse[109,126] in which disorders have been divided into congenital, exertional, neurologic, and endocrinologic categories. An alternative way is to classify accordingto the underlying pathophysiology, that is, disorders of excitation, action potential propagation, etc. Because knowledge of the pathophysiology of the various equine skeletal muscle disorders is limited, this system is of limited use. Practitioners may find approaching horses with muscle disorders from a problem-based approach most helpful. So horses are categorized into five categories: those having muscle cramping on exercise, those with gait alterations alone, those with muscle weakness, those with muscle wasting, and those with acute, severe rhabdomyolysiswith or without recumbency or death. These clinically based classifications are not mutually exclusive, and some disorders fall into more than one category. However, the author feels that this approach is the most comprehensive, considering the current volume of knowledge relating to muscle disorders in the horse.

Box 9-2 shows how the various equine skeletal disorders might be classified under the pathophysiologic system, using current information. Box 9-3 demonstrates a problem-based classification of the most common muscular disorders in the horse. One should note how many equine myopathies share common clinical presentations. Therefore a thorough genetic, environmental, and athletic history; physical examination; and laboratory workup are necessary to determine the most probable underlying cause in each case of muscle disease in the horse. Because the typical practitioner will be presented with a muscle-related problem, this chapter follows the classification set forth in Box 9-3. Before discussing the specific muscle diseases, the next section covers some general concepts and traditional thoughts concerning exertional rhabdomyolysis.

9.7.1 EXERTIONAL RHABDOMYOLYSIS

Exertional rhabdomyolysis refers to the syndrome of muscle cramping that occurs during physical exertion or exercise. Differential diagnoses for exertional rhabdomyolysis are extensive (Box 9-4). Terms used to describe the disorder include chronic exertional rhabdomyolysis, equine rhabdomyolysis syndrome, azoturia, Monday morning disease, tying-up, myositis, setfast, and chronic intermittent rhabdomyolysis.[65,92,127–129] Broadly, horses experience exertional rhabdomyolysis for two main reasons: the horse has an underlying myopathy (chronic exertional rhabdomyolysis) or the horse has been overexerted physically (sporadic exertional 476
rhabdomyolysis). Horses with underlying myopathies generally experience repeated episodes of rhabdomyolysis 477
after short bouts of exercise; therefore the condition may be characterized as chronic. However, horses that are overexerted may only experience a single episode in their lifetime because the bout of rhabdomyolysis is caused by physical and environmental circumstances as opposed to an underlying pathologic condition of the muscle.

9.7.1.1 BOX 9-2 CLASSIFICATION OF EQUINE MYOPATHIES ACCORDING TO CAUSE

I. Neurogenic: May be hereditary or environmental in origin, acquired, or congenital

- A. Disorders of anterior horn cells
- B. Disorders of motor nerve roots
- C. Peripheral neuropathies
- D. Disorders of neuromuscular transmission

1. Botulism
2. Tetanus

II. Myogenic

A. Traumatic
   1. Fibrotic myopathy
   2. Gastrocnemius muscle rupture
   3. Serratus ventralis muscle rupture
B. Inflammatory
   1. Sore or pulled muscles
C. Infectious
   1. Bacterial
      a. Clostridial myonecrosis
      b. *Streptococcus* spp.
         i. Abscessation
         ii. Autoimmune
         iii. Purpura hemorrhagica
         iv. Immunoglobulin G–mediated

2. Polymyopathy

Identifying horses with underlying myopathies that are characterized by chronic exertional rhabdomyolysisis a rapidly developing field of veterinary medicine. To date, three major syndromes have been described: RER in Thoroughbred horses, PSSM in Quarter Horsesand equine polysaccharide storage myopathy (EPSM) in Draft-breed horses. Horses that have chronic exertional rhabdomyolysis but that cannot be diagnosed with any of the three aforementioned disorders may be assumed to have a new or previously undescribed equine myopathy, provided no physical or environmental cause can be determined. Until more is known, horses with multiple bouts of rhabdomyolysis associated with minimal exercise that do not appear to fit into the categories ofRER, PSSM, 477
or EPSM are grouped and classifiedas having idiopathic chronic exertional rhabdomyolysis. One should not 478
assume that all Thoroughbreds, Quarter Horses, and Draft-breed horses demonstrating chronic or sporadic exertional rhabdomyolysis have RER, PSSM, or EPSM, respectively, simply because of their breed.

9.7.1.2

BOX 9-3 PROBLEM-BASED APPROACH TO HORSES WITH MUSCLE DISEASE

Disorders are grouped according to similar clinical appearance. (No category is mutually exclusive. Disorders are grouped by most common clinical presentation. The reader is directed to the text for more extensive discussion for each disorder/disease.)

I. Profound muscle cramping with exercise, tying-up syndrome, increased plasma/serum creatine kinase (CK) activity after exercise

A. Horses with underlying myopathy

1. Recurrent exertional rhabdomyolysis in Thoroughbreds

2. Polysaccharide storage myopathy in Quarter Horses

3. Equine polysaccharide storage myopathy in Draft Horses

4. Idiopathic chronic exertional rhabdomyolysis

5. Mitochondrial myopathy

B. Horses without underlying myopathy

1. Overexertion

2. Vitamin E or selenium deficiency
3. Electrolyte depletion

II. Horses with altered gait but without underlying myopathy and without muscle cramping, with or without elevated CK

A. Acute: muscle strain, sprain, tear

B. Chronic: fibrotic myopathy

III. Muscle weakness

A. Hyperkalemic periodic paralysis

B. Myotonia congenita and myotonia dystrophica

C. Equine motor neuron disease

D. Equine polysaccharide storage myopathy in Draft Horses (demonstrate primarily weakness)

IV. Muscle wasting

A. Generalized, may be accompanied by mild elevations in CK activity

1. Equine motor neuron disease
2. Streptococcal immune-mediated myositis: mediated by immunoglobulin G (IgG)
3. Cachectic atrophy
4. Disuse atrophy

B. Segmental

1. Neurogenic
2. Disuse atrophy
3. Fibrotic myopathy

V. Acute rhabdomyolysis, swollen painful musculature, with or without recumbency, with or without death

A. Severe, acute exercise-related rhabdomyolysis as from I.A. and I.B.

B. Malignant hyperthermia/postanesthetic myopathy

C. Clostridial myonecrosis

D. *Sarcocystis* spp.

E. Streptococcal immune-mediated myositis; Henoch-Schönlein (IgA) purpura

- F. Aortic-iliac thrombosis
- G. Toxic plants
  - 1 Cassia occidentalis
  - 2. White snakeroot
- H. Ionophore toxicity

VI. Disorders of the neonate

- A. White muscle disease/nutritional myodegeneration
- B. Foal rhabdomyolysis
- C. Glycogen branching enzyme deficiency
- D. Arthrogryposis

VII. Miscellaneous disorders

- A. Atypical myoglobinuria
- B. Postanesthetic myasthenia
- C. Polymyopathy
- D. Abscesses
- E. Tumors

In the past, exertional rhabdomyolysis in the horse was described in the literature under diseases of the liver, kidney, blood, or muscle. Exertional rhabdomyolysis also has been attributed to infection, cold weather, intoxication, nervous irritation, calcium deficiency, excess of glycogen, lactic acid poisoning, an increase in red blood cells, and an unbalanced alkali reserve.[130] Most theories have not undergone thorough scientific scrutiny to rule them in or out as an inciting cause, contributing factor, or primary cause.

Exercise is the common triggering factor in horses with exertional rhabdomyolysis. However, in horses with underlying myopathies the amount of exercise necessary to trigger muscle cramping is often minimal in contrast to healthy horses exhibiting a sporadic episode of rhabdomyolysis because of overexertion. Similarly, horses with underlying myopathies suffer from repeated episodes, whereas overexerted but otherwise healthy horses do not, provided they are not pushed repeatedly beyond their level of fitness. 478

9.7.1.4 Classic Theories for Exertional Rhabdomyolysis

For centuries horses were believed to tie up for a single as yet undetermined reason. The most popular reason was inactivity (i.e., stall rest) accompanied by a full ration of grain. This scenario was most likely to occur in Draft Horses rested on Sunday and worked on Monday, hence the name Monday morning disease. To date, the influence of diet, specifically carbohydrates, on exertional rhabdomyolysis is an area of active research. Diet plays a role in horses that are *predisposed* to exertional rhabdomyolysis from several different underlying myopathies (see specific disorders in the following sections), but how diet may influence muscle function in normal, healthy horses is still largely unknown.[126,131,132]

9.7.1.4.1

Lactic Acidosis

From 1914 to 1915 history records that when oats were scarce and raw sugar was fed to horsesas a substitute, the incidence of metabolic diseases, especially azoturia, increased.[134] In two papers that are much quoted in the literature, excessive glycogen buildup was postulated to result in an overproduction of lactic acid during exercise.[135,136] These studies reproduced the condition by feeding horses 3 kg of molasses daily and then exercising them after a rest period. However, in these studies the levels of lactate measured in horses experiencing rhabdomyolysis were similar or lower than the values currently measured in normal, healthy horses exercising anaerobically. Therefore, lactate alone is unlikely to trigger exertional rhabdomyolysis in healthy horses.[137] The role of lactic acid in horses with underlying myopathy has been investigated only in Thoroughbred horses with RER. That study found no correlation between lactate levels and CK activity measured 4 hours after exercise.[131] In investigations of other breeds of horses with chronic exertional rhabdomyolysis the relationships between rhabdomyolysis and lactate were less clear. [40,129,138,139]

9.7.1.4.2

Vitamin E and Selenium and Exertional Rhabdomyolysis

A relationship between equine rhabdomyolysis and vitamin E and selenium deficiencies has been claimed because of the reported success of supplementation in preventing further attacks.[140] Certainly vitamin E and selenium are essential to normal muscle function in all mammals. However, assuming that all horses thatsuffer from exertional rhabdomyolysis do so because of vitamin E and selenium deficiency is inappropriate. Muscle biopsy samples from horses with equine rhabdomyolysis, for example, have shown no deficiency in vitamin E or selenium.[141] No relationship between low blood glutathione peroxidase (GSHPx) activity and high AST levels has been found,[142] and the feeding of additional vitamin E does not decrease the frequency of high AST activities.[143] The claim that vitamin E and seleniumprevent or cure equine rhabdomyolysis therefore has been refuted.[12] A group of horses fed apparently low dietary levels of vitamin E for 4 months demonstrated no apparent clinical signs, no clinically abnormal levels of CK or AST were recorded, and the performance of the animals in standardized exercise tests was not compromised.[144]

In a survey of 144 animals thought to suffer from chronic rhabdomyolysis, 5 had lowered GSHPx activities. [12,105] However, these five animals also had abnormal urinary fractional electrolyte excretion values. Appropriate oral electrolyte and selenium supplementation resulted in no further clinical episodes. However, determining if this recovery would have occurred if either of the measures had been undertaken alone or if therapy had been withheld is not possible.

The literature poorly documents how commonly neurologic or myopathic conditions occur that may be related to chronic vitamin E or selenium deficiency. Disorders that have been attributed to dietary 479
deficiencies include equine motor neuron disease, equine degenerative myelopathy, neonatal nutritional 480
myodegeneration (white muscle disease), neonatal rhabdomyolysis, a predisposition to postanesthetic myopathy, and adult cases of exertional rhabdomyolysis. A case of severe masseter myonecrosis also has been attributed to selenium and vitamin E deficiency.[145]

Supplemental vitamin E may be beneficial in horses with underlying myopathies or healthy horses as an additional source of antioxidants in the diet. In fact, horsesin heavy work do appear to need more vitamin E

in their diet than many commercial feeds provide.[146] However, how chronic low vitamin E or selenium intake may affect performance in horses predisposed to rhabdomyolysisor in healthy horses is unknown. Therefore a common recommendation is to increase vitamin E intake in horses with chronic exertional rhabdomyolysis and healthy horses performing hard work even though the scientific work to uphold this recommendation has not been performed.

9.7.1.4.3 Role of Vitamin E and Selenium in Muscle Function

GSHPx, a selenium-containing enzyme, and vitamin E help protect cells against free radicals,[147] which are formed by the reduction of molecular oxygen during normal oxidative processes. The following is an example:

$$O_2 \rightarrow O^- \text{ (superoxide) enzyme}$$

A free radical (or reactive oxygen species) is any chemical substance that has an unpaired electron in its outer orbit. The presence of this electron makes the free radical inherently unstable. Superoxide radicals, for example, in solution form hydrogen peroxide by dismutation:

$$2O_2 + 2H^+ \rightarrow H_2O_2 + O_2 \text{ (superoxide dismutase)}$$

The superoxide radical also can react with hydrogen peroxide and hydrogen ions to produce the potent hydroxyl radical ($HO^\bullet$).

$$H^+ O_2^- + H_2O_2 \rightarrow O_2 + H_2O + HO\bullet$$

The hydroxyl radicals in turn can react with almost any organic molecule to produce other organic radicals via chain reactions.

Free radical reactions are responsible for a number of key biochemical events, including mitochondrial electron transport, prostaglandin synthesis, phagocytosis, and degradation of catecholamines. Under controlled circumstances free radicals are therefore necessary for life, but when uncontrolled they may result in a number of degenerative disease processes. For example, free radicals can cause irreversible denaturation of essential cellular proteins and lipid peroxidation of exposed polyunsaturated fatty acids within the phospholipid structure of cellular membranes, resulting in structural damage and the formation of further hydroperoxides. The cellular membrane damage in turn may result in the release of liposomal enzymes and further damage. The free radicals also can cause damage to hyaluronic acid and collagen, resulting in enhanced prostaglandin production, and they can uncouple oxidative phosphorylation and inactivate certain enzymes.

A system of natural antioxidant defenses is present within the body to counteract such free radical–induced damage, including GSHPx and vitamin E. GSHPx acts to reduce the production of hydroxyl radicals by reducing hydroperoxides to alcohols as part of a cyclic system re-forming glutathione. Within red blood cells the enzyme acts as an integral part of the system, protecting against the conversion of hemoglobin to methemoglobin by hydroperoxides. Vitamin E acts as a scavenger of free radicals, and vitamin C may assist by reducing the tocopheroxyl radicals formed by this scavenging. In addition, vitamin E helps block lipid peroxidation and also may form an important part of the membrane structure because of its interaction with membrane phospholipids. Other naturally occurring antioxidant defenses include chelators that bind to and decrease the concentrations of transition metals (e.g., iron).

Vitamin E and selenium deficiencies have been implicated in muscular problems in several species, especially sheep and pigs.[124,148] In the horse a myopathy attributed to vitamin E and selenium deficiency has been reported in foals from birth to 9 months of age.[149] The myopathy often is referred to as white muscle disease. In older animals, maxillary myositis, polymyositis, and dystrophic myodegeneration also have been attributed to such deficiencies.[150] However, some controversy exists over the role of vitamin E and selenium in such conditions. In foals the syndrome apparently has been well documented in geographic areas of known selenium deficiency and inadequate vitamin E intake,[151] although many foals raised in such areas may have decreased GSHPx activities and low blood selenium concentrations without being affected.[152]

Two common sources of free radicals during exercise are increased activity of xanthine oxidase during anaerobic degradation of purine nucleotides and the partial reduction of oxygen during oxidative phosphorylation within mitochondria. The precise mechanisms leading to muscle damage and fatigue during exercise are uncertain, although free radicals or reactive oxygen species possibly may play an important role. Following strenuous exercise, free radical production may exceed the capacity of the natural defense mechanisms of the cells, leading to muscle cell damage.

For many years scientists have appreciated that the human genetic muscular dystrophies share many
characteristics with the vitamin E and selenium deficiency myopathies in animals, although treatment of 480
patients with vitamin E so far has not been shown to be beneficial. However, with increased speculation that 481
free radical–mediated damage may be a factor in the cause or pathophysiology of the processes involved, a wide range of techniques has been developed to evaluate free radical damage. To date, no single method has been developed as the optimal way to study free radical processes. Perhaps because of the various techniques and differing criteria used for the choice of patients, few consistent abnormalities have been reported, especially respecting the measurement of antioxidant levels in blood or tissue.[153] The glutathione redox ratio has been suggested to be one of the most sensitive indices of oxidative stress, although reports have been inconsistent on the effects of exercise on the glutathione system in human beings, perhaps because of the varying fitness of the subjects and differences in the exercise intensity used. A study in the horse has suggested that exercise can induce changes in biochemical parameters (including the glutathione redox ratio) that indicate oxidative stress and the changes exacerbated during exercise at high temperatures and humidity.[154]

Vitamin E has an apparent protective effect on experimental damage to rat skeletal muscle and may act via a non–antioxidant mechanism, with the hydrocarbon chain being an important mediator of the effects seen.[155] An apparent protective effect occurs from supranormal extracellular vitamin E concentrations on normal rat muscle, and exacerbation of exercise-induced damage to skeletal muscle by vitamin E deficiency has been reported. Nutritional modification of skeletal muscle, perhaps by reduction of the unsaturation of skeletal muscle membranes or enhancement of the antioxidant status of muscles, or a combination of both, may help prevent or reduce calcium-induced skeletal muscle damage.[42] Artificial methods to reduce oxidant damage during exercise include the administration of exogenous sources of naturally occurring antioxidant defenses (e.g., vitamin E) and limiting the formation of free radicals by minimizing the formation of inosine monophosphate from purine degradation during exercises.

Type I and type IIA fibers are most likely to participate in excess free radical formation, because they are the most oxidative fibers and contain the most intracellular lipid stores. Selective type I fiber degeneration is found in nutritional myopathies of sheep and pigs that are responsive to vitamin E and selenium.[40]

Foals affected by exertional rhabdomyolysis have a significantly higher proportion of type 2C fibers and lower proportions of type 1 and type 2A fibers than healthy foals of comparable age.[156] These type 2C fibers include the undifferentiated fibers normally seen in foals and a proportion of previous type 1 and type 2A fibers, which appear as type 2C because of degenerative or regenerative processes. Some differences in the pathologic processes do appear to exist, however, between the equine conditions associated with vitaminE and selenium deficiencies and those in other species. Vitamin E deficiencies in calves and chicks show mitochondrial alterations early in the condition. In vitamin E– and selenium-deficient lambs and chickens, the earliest changes occur in small vessels, connective tissue, and neuromuscular elements. In the horse the changes appear to affect the myofibrilsfirst. Morphologic changes in mitochondria and the sarcoplasmic reticulum seem only to occur in fibers with advanced lesions.[156,157]

Factors that may predispose horses to a vitamin Eand selenium deficiency include rancid feed, the addition of fish or plant oil to the feed, prolonged storage of grain (e.g., dry grain loses tocopherol activities far more slowly than moist grain), poor-quality hay, and lush pastures.[126] Pastures associated with acid, poorly aerated soils, soils with a high sulfur content, or volcanic rock are more likely to be selenium deficient. Cases of deficiency are more likely to occur in areas with low (<0.05 ppm) plant selenium content. Dietary levels of selenium may be misleading, however, not only because other factors are likely to be involved in the pathogenesis of the condition but also because the biologic availability of the various types of selenium have not been determined. In addition, high but nontoxic levels of copper, silver, tellurium, and zinc possibly could interfere with selenium availabilityand therefore induce typical lesions in animals on diets containing amounts of selenium usually considered to be adequate.

Probably other factors such as stress (including managemental regimens and environment) and increased physical activity may be important for expression of clinical signs in the face of a deficiency and may explain why two similar groups of animals receiving the same dietary intake can show different clinical responses to the amounts of vitamin E and selenium. Acute selenium toxicity in the adult horse also may be associated with myodegeneration plus pulmonary edema, gastroenteritis, hepatic degeneration, and necrosis.[126,157]

9.7.1.4.4 Hypothyroidism

Muscular problems are a common symptom of hypothyroidism in human beings.[158,159] In mild human cases, fatigue may be the only presenting symptom, although more severe cases may be accompanied by overt muscle cell damage, increased resting plasma CK activities, and sometimes increased myoglobin levels.[160] Poor racing performance and certain myopathies have been related to mild secondary hypothyroidism,[161] although this conclusion has been challenged.[162] Oral thyroxine supplementation may improve performanceor decrease the incidence of myopathies in cases of hypothyroidism.[109,161] However, considerable debate still exists as to whether hypothyroidism is important in the pathogenesis of exertional myopathies in the horse.[65] 481

482

Resting thyroxine concentrations did not differ significantly between animals believed to be suffering from chronic rhabdomyolysis and those suffering from a variety of other conditions. However, some rhabdomyolysis sufferers may have a lowered response to thyrotropin-releasing hormone,[105] which may reflect a decreased thyroid reserve, but too few cases have been investigated to date. A recent study examined exercise in thyroidectomized horses. Exercise intolerance was documented; however, increases in

CK activity were not.[163] Conversely, in the author's experience, oversupplementation may lead to iatrogenic hyperthyroidism and symptoms of mildly increased CK activity and muscle wasting.

9.7.1.4.5

Viral Causes

Muscle pain or myalgia is a common symptom in the acute phase of influenza and other viral illnesses in human beings, although few reports of severe muscular problems are available.[51,164,165] Myalgia and myoglobinuria have been observed with herpesvirus infections.[51] Some horses are stiff and unwilling to work during or after an attack of the virus.[166] Viral infection has been reported as being one of the predisposing factors to equine rhabdomyolysis.[167]

A clinical investigation of an outbreak of muscle stiffness and poor performance in a flat-racing stable of Thoroughbreds revealed that more than one third of the horses demonstrated signs of muscular stiffness over2 months, and 64% at one or more of the sampling times had increased CK and AST activities.[168] Serologic tests were highly suggestive of an equine herpesvirus type 1 infection. The possibility of a viral cause, at least in outbreaks of stiffness in racing yards, needs more in-depth evaluation. The virus could affect muscle directly, resulting in an increased susceptibility to exercise-induced damage. Alternatively, the increase in blood viscosity observed after infection could result in an impaired blood flow and decreased oxygen delivery to the peripheral tissues.[169] A recent study of horses exercised after experimental infection with equine influenza virus failed to demonstrate significant effects on muscle function or CK activity or evidence of muscle stiffness.[170]

9.7.1.5

Treatment of Rhabdomyolysis

Treatment of rhabdomyolysis depends on the underlying cause. For example, horses experiencing muscle damage because of sepsis or trauma require different approaches than horses experiencing rhabdomyolysis caused by underlying, heritable myopathies. Horses with rhabdomyolysis often have colic or nonspecific signs. Other differential diagnoses include disorders that frequently are associated with depression or a reluctance to move and include but are not limited to anthrax infection, postcastration abscesses, colic, cystitis, neurologic disorders, lymphadenitis, laminitis, nephritis, pleuritis, acorn poisoning, tetanus, and skeletal lamenesses.

The practitioner should perform a thorough physical examination and obtain a detailed history. The initial workup of a horse suspected of having rhabdomyolysis should include a complete blood count, chemistry profile, and urine collection. Treatment should follow the observations made on physical examination and changes observed in the blood count and chemistry profile. The practitioner should rehydrate horses with significant dehydration with fluids that reflect any deficiencies identified on the chemistry profile and should treat horses in significant discomfort with nonsteroidal antiinflammatory drugs (NSAIDs), provided renal perfusion and function are supported. The practitioner should not treat horses experiencing rhabdomyolysis in the face of extreme exhaustion and dehydration with nephrotoxic medications (aminoglycosides and NSAIDs) until ascertaining renal function. Horses that typically fall into this category include those with capture myopathies (e.g., horses that are trapped and struggle in trailer accidents, get wrapped up in fences, are being taught to tie to a fixed object, or get cast in a stall) and endurance horses. Treatment for horses with mild cases of rhabdomyolysis includes keeping them warm, minimizing movement, and providing stall rest and NSAIDs as appropriate. Muscle enzyme activity and the physical response of the horse to being asked to move and exercise can guide the practitioner as to when returning the horse to normal physical activity is appropriate.

Therapies specific to each type of rhabdomyolysis are discussed in their respective sections.

9.8 Horses With Underlying Myopathy

9.8.1 RECURRENT EXERTIONAL RHABDOMYOLYSIS

Racing Thoroughbreds share a high degree of relatedness. As much as 80% of the genome of the modern Thoroughbred directly traces to 31 animals.[171] This extensive amount of linebreeding makes associating diseases with a particular ancestor difficult because so many horses healthy or not may be related to that individual. The suggestion has been made that many Thoroughbred horses share a similar genetic trait that leads to RER.[132,172] Epidemiologic surveys of racing Thoroughbreds support that exertional rhabdomyolysis is so common, it may affect as much as 5% of the racing Thoroughbred population, and that the majority of these horses likely have the same condition referred to as recurrent exertional rhabdomyolysis.[117]

9.8.1.1 Clinical Signs and Laboratory Findings

Thoroughbred horses with RER may have mild to moderate signs of muscle cramping. Clinical signs of RER are similar to other horses exhibiting exertional rhabdomyolysis. The predominant clinical signs are mild to 482

483

severe muscle cramping of the major muscle groups of the hindquarters including the gluteal, semimembranosus, semitendinosus, biceps femoris, and quadriceps femoris muscles. Involvement of these muscle groups is not exclusive, and muscle cramping of the forelimb musculature may occur. Cramping is associated with mildto severe pain, manifested by anxiety, profuse sweating, refusal to move, and increased heart and respiratory rates. Affected muscles are firm and painful on palpation. The practitioner can palpate generalized or focal areas of flocculation that may be associated with focal areas of muscle tearing or edema. In mild to moderate cases muscle contractures abate within several hours, and the horse moves about more comfortably. In severe cases, rhabdomyolysis may lead to recumbency, necessitating a prolonged convalescence, which in turn may lead to further complications. Recovery is related to the severity of muscle fiber necrosis and may take days to weeks in mild and moderate cases and months in horses with severe rhabdomyolysis. Repair begins with migration of satellite cells from their position under the basement membrane and their transformation into myoblasts. Disruption of the muscle cell basement membrane rarely occurs even in severe cases of exercise-induced rhabdomyolysis. However, should damage to the basement membrane occur, the defect would heal largely with connective tissue.[173] In most cases, horses readily return to athletic function.

Damaged muscle fibers release myoglobin and the intracellular enzymes LDH, AST, and CK into the circulation. Myoglobin is filtered by the kidneys and is excreted in the urine. With moderate to severe muscle necrosis myoglobin causes the urine to be orange to brown. In horses with systemic acidosis and dehydration that suffer significant muscle damage, myoglobin may cause tubular nephrosis with acute or delayed renal damage or failure.[174] In Thoroughbreds with RER, onset of rhabdomyolysis occurs early, during aerobic exercise, and for this reason no accompanying systemic acidosis or dehydration occurs and renal damage is rare. Tubular nephrosis rarely occurs, presumably because myoglobin does not precipitate out in the urine of the adult horse.

Elevations in serum enzymes and myoglobin are proportional to the amount of muscle damage, with serum myoglobin levels rising most rapidly. Myoglobin assays are not used frequently in clinical situations because

of the difficulty of measuring equine myoglobin and because the half-life of myoglobin in the serum is short, with peak levels occurring minutes after exercise. LDH and AST activity are less specific indicators of muscle damage than CK or myoglobin because they also are released with liver damage. In clinical situations, CK and AST activity are the most frequently measured enzymes used to evaluate muscle necrosis. CK and AST are included in conventional serum or plasma chemistry profiles and can provide clues as to the length of time since the initial insult. Serial elevations of CK and AST indicate ongoing muscle necrosis. After an episode of rhabdomyolysis, CK levels increase exponentially from the reference range to levels as high as 100,000 U/L. CK is a sensitive indicator of muscle damage, with activity peaking 4 to 6 hours after insult. If muscle necrosis is not ongoing, CK levels decrease rapidly over the next 24 to 48 hours because of the relatively short (108-minute) half-life. Serum AST activity takes 12 to 24 hours to peak, and activity may remain elevated for 7 to 14 days after insult.[39]

In Thoroughbred horses with RER, CK activity appears to peak 4 to 6 hours after activity and affected horses have intermittent elevations in CK activity that are not associated with clinical signs of muscle cramping (subclinical exertional rhabdomyolysis).[175] Subclinical exertional rhabdomyolysis is common in Thoroughbred horses with RER, and CK activity may be as high as 10,000 U/L. Normal healthy horses participating in race trainingalso may have occasional increases in CK activity butdo not appear to have them as frequently as horseswith RER.

9.8.1.2 Causes

A group of Thoroughbreds with a history of chronic exertional rhabdomyolysis recently were studied and were found to have similar abnormalities.[132,176] Muscle biopsies of the middle gluteal muscle did not identifyany abnormal accumulations of polysaccharide, but an increased number of centrally located nuclei were found in mature muscle fibers. In vitro contracture studies demonstrated increased sensitivity to caffeine and halothane and faster times to peak contraction and 50% and 90% relaxation compared with healthy Thoroughbred horses or Quarter Horses with PSSM.[177] The in vitro contracture study now is considered the gold standard for diagnosing RER in the Thoroughbred horse.

The muscle contracture results are similar to pigs with malignant hyperthermia.[178] However, further testing has demonstrated that the cellular defect in Thoroughbreds with RER and pigs with malignant hyperthermia is different. Therefore RER represents a disorder similar but not identical to malignant hyperthermia in swine.[179]. Of interest is that occasional incidences of malignant hyperthermia in Thoroughbred horses with chronic exertional rhabdomyolysis have been reported.[180–185] This may indicate that Thoroughbred horses with RER may be more susceptible to episodes of malignant hyperthermia while under general anesthesia, but the incidence is far less common than in swine.

The exact cellular mechanism that leads to RER in Thoroughbred horses has yet to be elucidated, and genetic studies are currently under way. Possibly the defect lies in calcium regulation within the cell at the level of the dihydropyridine or ryanodine receptor, but this has yet to be confirmed. 483 484

9.8.1.3 Pathophysiology

RER affects as much as 5% of the racing Thoroughbred population and likely is inherited as an autosomal dominant trait.[117,172] However, expression of the disorderis multifactorial and depends on the fitness level and exercise schedule of the horse, diet, age, gender, temperament, and the presence of any skeletal lameness.[117]

Expression of RER in Thoroughbred horses has been postulated to be related to the physicochemical changes experienced by the body during a high level of stress or anxiety. Such a trigger would be similar to that seen in swine with malignant hyperthermia. However, the exact mechanism of how anxiety may trigger exertional rhabdomyolysis in susceptible horses remains unknown.

Many of the factors listed previously may influence the mental and physical state of the horse. For example, the typical Thoroughbred horse with RER has longbeen described as a 2- or 3-year-old filly with a nervous temperament.[65,66,117,186] A recent epidemiologic survey carried out in the United Kingdom showed that females are more likely than males to suffer from this condition, particularly in the birth to 2-year-old and 5- to 6-year-old age groups.[105,187] However, an equal sex ratio was reported in another study.[188] Genetic studies support that RER likely is inherited as an autosomal dominant trait.[172] The increased expression of RER in female Thoroughbreds and in younger horses might be because of temperament. Fillies are more likely to be describedas having a nervous temperament by their trainers, and young horses may find the race track environment stressful.[117]

Diet also influences expression of RER, and affected horses often consume quantities of grain in excess of10 pounds (4.5 kg) per day. Higher CK activity has been documented in horses with RER compared with control horses when both groups were fed diets high in carbohydrates. In addition, dietary studies have shown that feeding horses diets high in carbohydrates at levels at which the caloric intake exceeds body demands may accentuate nervousness. This effect has been observed in Thoroughbreds with RER and in normal healthy horses.[175] Conversely, horses with RER that are fed diets higher in fat demonstrated a decrease in CK activity, and horses with RER and healthy horses consuming diets high in fat often are regarded as being more calm and less fearful.[131] A number of high-fat, low-carbohydrate commercial grain mixes are now available for the horse owner, and anecdotal reports support laboratory findings that the number of incidences of rhabdomyolysis in horses with RER consuming these diets are fewer. Whether the influence of diet on the expression of RER is caused by temperament alone, another factor, or a combination of factors has yet to be determined.

Racehorses with RER are more likely to have an episode of rhabdomyolysis when exercised at a medium gallopas opposed to walking, trotting, breezing, or racing. Horses with RER that are exercised at the trot were more likely to have increased CK activity than when galloping at high intensity. The influence of temperament also may be a factor. Thoroughbreds at the race track are often trotted against traffic as a warm-up and then are turned around to gallop back home at a controlled rate of speed. This training scenario was the most frequent form of exercise associated with episodes of rhabdomyolysis and may result from excitement or anxiety that triggers the episode of rhabdomyolysis in susceptible horses. Horses that are fit for racing may find this training scenario especially exciting because they often pull and try to run faster. When racehorses were allowed to gallop full out as in breezing or racing, episodes of rhabdomyolysis were infrequent.[117]

Horses with an underlying lameness are predisposed to episodes of exertional rhabdomyolysis. Whether changes in gait may be related to muscle pain or soreness or whether underlying skeletal disorders may alter a horse's way of going, precipitating an episode of rhabdomyolysis, or whether running in pain from a skeletal disorder may trigger an episode of rhabdomyolysis is unclear.

Inclement weather often has been cited as causing an increase in the incidence of RER, as has the time of year.[127,130] In a 2-year survey in the United Kingdom, significantly more episodes of rhabdomyolysis were reported from November to February than during other times of the year.[105,187]

At the race track, large groups of horses are fed, exercised, and housed under similar conditions. Yet some are particularly predisposed to chronic exertional rhabdomyolysis, which underscores the likelihood of a genetic basis for the disorder. One is tempted to assume thatall affected Thoroughbreds at the racetrack have RER. However, the practitioner must be wary about diagnosing all Thoroughbreds with chronic exertional rhabdomyolysis as having RER until the genetic fault is identified and a genetic test is available.

9.8.1.4 Diagnosis

Currently, the gold standard for diagnosing RER is the caffeine or halothane muscle contracture test.[176] However, this test requires a biopsy sample from intercostal muscle and is not readily available. Therefore diagnosis of RER is based on history, laboratory documentation, and histopathologic examination of muscle. Horses with RER should be Thoroughbreds or Thoroughbred crosses, because of the likelihood the disorder is inherited as an autosomal dominant trait. The horse should have experienced multiple bouts of muscle cramping after nonintensive exercise accompanied by documented elevations in CK activity. Muscle biopsy reveals an increased number of central nuclei without evidence of PSSM.

484
485

9.8.1.5 Treatment

Treatment of horses with RER aims at managing the frequency of the clinical episodes of rhabdomyolysis, considering that the disorder is likely a primary myopathy. Environmental and dietary factors appear to influence the expression of RER. Such factors include dietary fat and carbohydrate content, dietary electrolytes, exercise regimens, housing and turnout conditions, and underlying skeletal lameness. The practitioner must pay particular attention to the temperament of the individual horse. The most successful trainers modify the affected workout schedule of the horse to minimize stress. For example, horses that prefer to work alone or with company should do so. If a horse is calmer to work when the track is empty, the trainer should exercise it early in the day; others may benefit from a long, slow warm-up to minimize stress. One should make similar stress-reducing modifications for affected horses used in other disciplines.

One should modify the diet to provide adequate but not excessive amounts of calories for the level of work being performed such that a greater proportion is supplied from fats as opposed to carbohydrates. High-calorie diets composed primarily of fat are effective in decreasing postexercise CK activities in affected horses.[189] The optimal fat source and percentage of fat in the diet have yet to be determined, but several commercially available feeds on the market have been found to be useful. The exact mechanism by which increased dietary fats lower CK activity in horses with RER has yet to be determined.

Dantrolene has been used in human medicine to treat and help prevent malignant hyperthermia. In this condition an abnormal release of calcium from the sarcoplasmic reticulum appears to occur, resulting in prolonged contracture, hyperthermia, metabolic and respiratory acidosis, and muscle damage. Dantrolene is thought to decrease the rate of calcium release from the sarcoplasmic reticulum and to affect charge movement in the T tubule system. Dantrolene has been used in human beings to treat chronic exertional rhabdomyolysis.[190] Controlled studies examining the use of dantrolene in RER are being performed. Until these are reported, the guidelines cited next have been shown anecdotally to be efficacious.

Although dantrolene sodium has been suggested for treating equine rhabdomyolysis, the drug is used more commonly in prevention. Giving 2 mg/kg/day diluted in normal saline by a stomach tube for 3 to 5 days and then every third day for a month has been recommended.[65,191] A lower daily dose (300 mg) may be equally

beneficial[191] and perhaps preferable because the drug is hepatotoxic.[65] Another recommendation is 500 mg orally for 3 to 5 days and then 300 mg every thirdday for a time. The time period depends on the circumstances and the effect on the liver, but prolonged treatment is not recommended. Monitoring of hepatic status and function is recommended because the effects on the liver seem to be individually variable. Up to 1 g of dantrolene, given with a small feed 1½ to 2 hours before exercise for 3 to 5 days has been used with apparent success in racehorses in the United Kingdom, but in some cases the horses may have been suffering from overexertion, for example, rather than RER. Such doses have been suggested to be unlikely to reach therapeutic levels. The drug appears not to be as bioavailable in the horse as in human beings and is cleared more quickly.[181] One must take care with dantrolene because its use and efficacy remain uncertain.

9.8.2 POLYSACCHARIDE STORAGE MYOPATHY

PSSM is a recently described and apparently common disease of Quarter Horses and Quarter Horse–related breeds such as the Paint Horse and Appaloosa.[132] The disease is characterized by repeated episodes of exertional rhabdomyolysis that in some cases may be inducedwith little exercise. Increased CK activity in the plasma or serum accompanies episodes of rhabdomyolysis. The most distinctive characteristic of the disease is a mild to severe accumulation of abnormal polysaccharide within the myoplasm. Studies are ongoing to characterize the disorder and to describe a likely candidate gene and hopefully the development of a genetic test.

9.8.2.1 Clinical Signs and Laboratory Findings

Horses with PSSM have frequent episodes of muscle cramping and rhabdomyolysis. Clinical signs and laboratory changes (increased muscle enzymes, myoglobinuria) associated with an episode of PSSM rhabdomyolysis look similar to other causes of rhabdomyolysis. Mild episodes are characterized by a stiff gait, anxiety, and stretching out in stance. More severe episodes are characterizedby anxiety, painful behavior, sweating, and reluctance to move or recumbency. Horses appear to vary in the severity or expression of the disorder. Some horses also appearto tolerate exercise better than others despite similar changes in CK activity after exercise. This may reflect a tolerance of the individual horse to muscular discomfort associated with exercise. Episodes are especially prevalent when exercise intensity increases.

Horses that experience frequent episodes of rhabdomyolysis and have considerable accumulations of abnormal
polysaccharide storage within the muscle fibers may have persistent elevations in serum or plasma CK 485
activity. Whether this represents ongoing subclinical rhabdomyolysis or an alteration in the permeability of the 486
muscle cell membrane is unknown.

Muscle biopsy of horses with a history of chronic exertional rhabdomyolysis is indicated. Horses with PSSM have subsarcolemmal accumulations of an abnormal polysaccharide that is visible with a periodic acid–Schiff stain.

9.8.2.2 Causes and Pathophysiology

Evidence supports that PSSM is heritable.[192,193] In addition, the accumulations of abnormal polysaccharide observed in periodic acid–Schiff stained muscle sections appear to increase with age and therefore may be a secondary feature of the disease. Significant accumulations of abnormal polysaccharide may not be visible until3 years of age in some horses, despite documented intermittent exercise-associated increases in serum and plasma CK activities at a younger age. Affected horses show great variability in expression of the disorder as

reflected in the amount of abnormal polysaccharide observed in muscle sections, desire and ability to exercise, frequency and severity of episodes of rhabdomyolysis, and degree of elevations in CK activity.

The cause of PSSM appears to be related to glucose metabolism as opposed to calcium regulation as has been documented in Thoroughbred horses with RER. Overall, affected horses demonstrate greater total muscle glycogen content compared with control horses. In addition, when fasted, horses with PSSM have consistently lower blood glucose concentrations than healthy controls. When given intravenous or oral glucose, horses with PSSM cleared the glucose from the blood stream at a faster rate than healthy controls. When administered insulin, horses with PSSM became severely hypoglycemic and remained so longer than healthy control horses. Why horseswith PSSM have an increased sensitivity to insulin is unknown. However, this increased sensitivity results in increased uptake of glucose into the muscle cell. When the muscle cell takes up glucose from the blood, glycogen synthase but not glycogen branching enzyme is stimulated. Glycogen synthase is responsible for forming the straight chains of glucose in glycogen, whereas glycogen branching enzyme is responsible for the branching points. The abnormal polysaccharide within the muscle cell appears to be long straight chains of glucose molecules compared with the normal branched configuration of glucose molecules that compose glycogen. Horses with PSSM can break down the abnormal glycogen for energy. The accumulation of abnormal glycogen appears to lie in the fact that with few branches, only a few points exist on which the enzymes responsible for breaking down glycogen can act, coupled with increased formation resulting from the increased cellular uptake of glucose. Horses with PSSM have glycogen branching enzyme with apparently normal activity.

Exercise influences glucose uptake into muscle cells. The physiologic changes associated with exercise result in changes in the number and activity of glucose transporters within the muscle cell membrane. Horses with PSSM have glucose tolerance curves more similar to healthy controls when they are exercised regularly,[194,195] which may explain why regular exercise and maintaining a certain level of fitness appears to help affected horses. Diets high in fat also appear to help these horses and may be related to a less severe postprandial glycemic response and decreased uptake of glucose by muscle cells. The exact cellular defect that results in increased uptake of glucose into the muscle cell is undetermined.

9.8.2.3 Diagnosis

A genetic test has yet to be developed to diagnose horses with PSSM. Therefore diagnosis generally is based on appropriate genetic heritage, repeated bouts of exertional rhabdomyolysis, and the presence of abnormal polysaccharide on a periodic acid–Schiff stained muscle biopsy. Because the accumulation of abnormal polysaccharide appears to be a secondary feature of the disease, accurately diagnosing affected horses until 3 years of age or more may not be possible. Some anecdotal evidence supports that mildly affected horses fed diets low in carbohydrates may accumulate polysaccharide in smaller amounts or more slowly than other affected horses. Details concerning what factors influence the expression of the disorder and the role different diets have on the accumulation of abnormal polysaccharide have yet to be investigated.

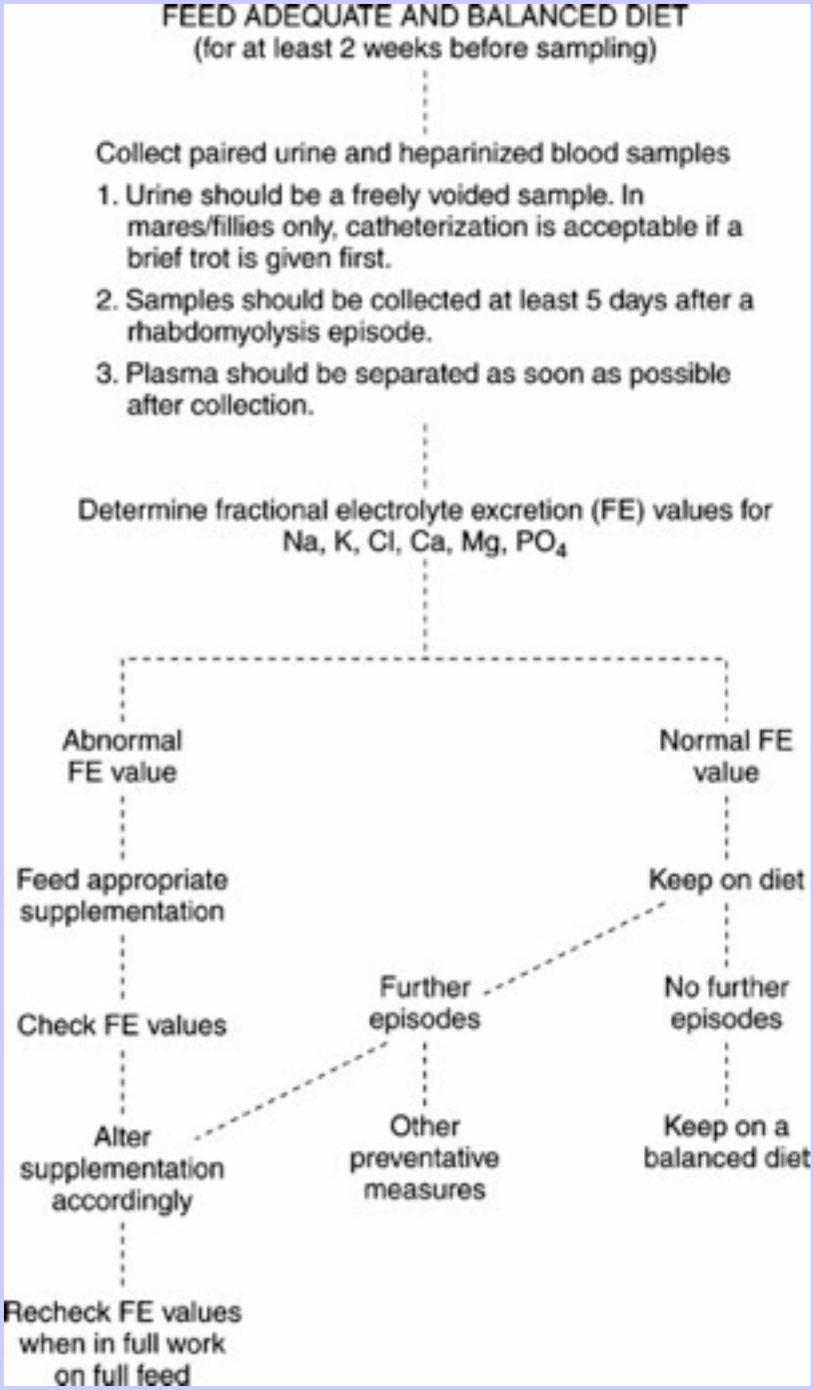
An exercise tolerance test can be a useful diagnostic tool in horses with PSSM. Affected horses commonly experience a doubling or more of baseline CK activity after 15 minutes of trotting on a lunge line. The practitioner draws blood before and 4 to 6 hours after the exercise. The practitioner also should have fractional excretions of electrolytes (Figure 9-4), measurements of serum selenium (or GSHPx activity), and vitamin E concentration determined on horses with PSSM. One should supplement dietary electrolytes and selenium and vitamin E intake if these are abnormal.

9.8.2.4 Treatment

Horses with PSSM have a heritable myopathy that in many horses can be managed readily. Because of the nature of the disorder, the practitioner should counsel owners, trainers, and riders of affected horses that the horse may not be able to perform at elite levels of competition if the condition is severe. However, many horses do perform well and only have occasional episodes of rhabdomyolysis. One should exercise horses regularly because a good level of basal fitness appears to protect against episodes and should increase the 486
exercise intensity slowly. Horses may live in stalls, but living outside where the horse may move around 487
readily appears to lessen the frequency of episodes of rhabdomyolysis.

The practitioner should modify the diet to provide adequate calories for the level of activity of the horse and moreover should limit the intake of carbohydrates. Many horses can do well consuming only a grass or alfalfa hay and a simple vitamin and mineral supplement. If additional calories are necessary, they can be supplied as fats. Many different fat sources are available and include corn or vegetable oils, linseed oil, or rice bran. Commercial grain mixes that are high-fat, low-carbohydrate feeds are available and may be a good source of fat for the horse without the concern associated with other sources of fat. Oils can spoil, and larger quantities of oils or rice bran may not be palatable for some horses.

Figure 9-4 Protocol for using the fractional electrolyte excretion test in clinical cases of the equine rhabdomyolysis syndrome. One should not evaluate the electrolyte statuswithout also evaluating Vitamin E and selenium status.



9.8.3

EQUINE POLYSACCHARIDE STORAGE MYOPATHY

EPSM is the term currently used for a disorder described in Draft-breed horses.[196,197] Although histopathologic abnormalities of muscle biopsy samples are similar with these two disorders, clinical signs and apparent incidence in the two breeds are different.

9.8.3.1

Clinical Signs and Laboratory Findings

EPSM has been described in Draft Horse breeds including Belgians, Percherons, Clydesdales, Shires, Haflinger, Norwegian Fjord, Suffolk, Irish Draft, Draft crosses, and a Draft mule. Depending on the description of the abnormal periodic acid–Schiff positive staining polysaccharide on muscle biopsies, the incidence of EPSM in the general Draft Horse population has been estimated to be 45% to 66%. Whether this form of polysaccharide storage disease occurs in other breeds has been debated.

Clinical signs of EPSM appear to take two forms. Draft Horses with EPSM may exhibit exercise-associated muscle cramping similar to that observed in other types of exertional rhabdomyolysis. Complications from rhabdomyolysis are similar to those described in other horses with severe rhabdomyolysis and include postanesthetic recumbency, renal failure, and laminitis. EPSM is associated with a second clinical syndrome in Draft Horses characterized by progressive poor performance, shivers or a shiverslike gait, progressive muscle wasting, muscle weakness, recumbency, and death (Figure 9-5). Serum or plasma CK activities are increased in horses with EPSM demonstrating either syndrome and vary from mild to severe depending on the degree of rhabdomyolysis.

Figure 9-5 Draft Horse with equine polysaccharide storage myopathy standing with a base-narrow, weak stance.

9.8.3.2
Causes and Pathophysiology

The underlying defect causing EPSM has not been determined. Glucose tolerance tests similar to those reported in Quarter Horses with PSSM have not been performed. Therefore whether the defect in Quarter Horses with PSSM and Draft Horses with EPSM are similar or distinct is unknown. Similarly, detailed familial studies have not been performed. As much as 66% of the Draft Horse population has been described as having abnormal polysaccharide within muscle cells on biopsy. The finding has been described in a referral hospital necropsy population and from muscle biopsies from apparently healthy horses without a history of muscle-related problems. This raises the question of whether Draft Horses as a population are linked closely genetically and therefore a large percent of the population has a similar genetic defect or whether the clinical syndrome results from another cause and the high incidence of abnormal polysaccharide within the muscle fibers is an innocent finding. No other species have been described as having innocent accumulations of polysaccharide intracellularly, so probably the aforementioned explanation is plausible. Further investigation is necessary to define this disorder in Draft Horses more clearly.

9.8.3.3
Diagnosis

Diagnosis of EPSM is based on appropriate genetic heritage, presence of abnormal glycogen accumulation in muscle biopsy specimens, increased serum and plasma muscle enzyme activity, and presence of appropriate clinical signs. Review of muscle biopsies obtained from Draft Horses at postmortem examination suggests that EPSM may affect as many as 45% to 66% of Draft Horses.

9.8.3.4
Treatment

Treatment of Draft Horses with EPSM involves dietary changes, primarily increasing fat intake. Increased fat intake was supported in one study that used spot checks ofCK activity demonstrating a generalized lowering of CK values and a history of fewer episodes of rhabdomyolysis.[196] As with other causes of chronic rhabdomyolysis, the practitioner should optimize the electrolyte, vitamin E, and selenium intake of the horse. Because of the high incidence of abnormal polysaccharide within the muscle, the suggestion has been made that all Draft Horses should consume diets that are low in carbohydrates and highin fats.

9.8.4
IDIOPATHIC CHRONIC EXERTIONAL RHABDOMYOLYSIS

Horses of many breeds and types other than Thoroughbreds, Draft Horses, and Quarter Horses may experience recurrent episodes of exertional rhabdomyolysis. Of special note are Standardbred and Arabian horses. These breeds share some common genetic heritagewith Thoroughbred horses, and individuals with chronic exertional rhabdomyolysis may have muscle biopsy findings consistent with RER. These individual horses may respond favorably to management changes (high-fat diet and regular exercise) recommended for Thoroughbreds with RER. However, muscle contracture testing of affected Standardbred and Arabian horses has not been performed to confirm similar muscle pathophysiology.

Some Warmblood breeds with chronic exertional rhabdomyolysis have abnormal polysaccharide evident within muscle fibers on muscle biopsy. Clinically, these horses resemble Quarter Horses with PSSM as opposed to Draft Horses with EPSM. However, many Warmblood horses share genetic history with Draft breeds. Glucose tolerance testing of Warmblood horses with abnormal polysaccharide has not been performed. Affected

Warmblood horses often are managed with high-fat diets and regular exercise as described for Quarter Horses with PSSM.

Some horses with idiopathic exertional rhabdomyolysis do not respond to management and dietary recommendations described previously. Practitioners should counsel owners of horses that suffer from repeated episodes of rhabdomyolysis despite multiple management changes to decrease the exercise intensity the horse is performing or retire the horse from regular work.

9.8.5 MITOCHONDRIAL MYOPATHY

A small family of horses has been described with a syndrome of severe exercise intolerance. In this family one mare was found to have a deficiency of complex I respiratory chain enzyme. She had severe exercise intolerance and muscle stiffness with extreme lactic acidosis in relationship to the degree of exercise, but without rhabdomyolysis. Muscle biopsy demonstrated large accumulations of mitochondria with bizarre cristae formations. Biochemical analysis revealed low activity of nicotinamide adenine dinucleotide coenzyme Q reductase, the first enzyme complex of the mitochondrial respiratory chain, which resulted in impaired oxidative capacity for exercise and heavy reliance on anaerobic metabolism for muscular energy.[198] Examination of related horses provided evidence that the condition was likely familial.

9.9 Horses Without Underlying Myopathy

9.9.1 OVEREXERTION

Overexertion may be defined as physical exertion to a state of abnormal exhaustion. Many horses willingly work to a point where they are too exhausted to go on. If a horse is worked to a point of exhaustion, especially in an environment of heat and high humidity, multiple organ failure may result. Rhabdomyolysis is a frequent 488
component of overexertion. Rhabdomyolysis may be precipitated from glycogen depletion and electrolyte 489
depletion. Because horse sweat is hypertonic, profound and prolonged exercise leads to significant electrolyte depletion. Lactic acidosis induced by dehydration and anaerobic glycolysis further complicates electrolyte depletion. Laboratory tests typically reveal muscle enzymes 10 to 1000 times greater than normal; depletion of sodium, potassium, and chloride; and dehydration. Muscle biopsy demonstrates acute rhabdomyolysis without evidence of previous rhabdomyolysis. Horses require emergency resuscitative therapy including intravenous fluids and restoration of electrolytes. Horses in anuric or oliguric renal failure may respond favorably to furosemide or dopamine therapy.

The exhausted horse syndrome tends to occur when horses have been pushed past their performance limits. The syndrome is believed to have a complex etiology involving a combination of fluid and electrolyte losses, depletion of energy stores, and extremes of environmental conditions. The syndrome therefore usually occurs in association with Three-Day Events and long-distance rides.[167,188] A brief summary of some of the possible contributing factors follows. More detailed information is available.[169,199–201] The amount of sweat produced by an exercising horse depends on the environmental conditions, nature of the work, and the fitness of the animal. Under favorable climatic conditions, sweat loss can be on the order of 5 to 8 L/hr on long-distance rides. In hot, humid conditions, where sweating is partially ineffective, sweat production can be as high as 10 to 15 L/hr. An endurance horse can lose at least 25 to 30 L or more if conditions are unfavorable, which far exceeds the 1 to5 L lost by a racehorse performing a sprint at top speed. Early on in exercise and when the sweat losses are low, much of the water loss can be made up by absorptionof water from the large intestine. However, if water losses

via sweat are between 5% and 10% of body weight, a decrease in circulatory volume occurs. The decrease tends to occur after about 3 hours of exercise with moderate sweating but occurs much sooner during exercise in high heat and humidity.

Sweat contains low concentrations of calcium and phosphate but is hypertonic to plasma with respect to sodium, potassium, and chloride. During exercise, the horse appears to be able to maintain, initially at least, its plasma electrolyte concentrations at the expense of other body compartments. This is especially true for sodium, for which the contents of the gastrointestinal tract are believed to provide an important reservoir. Decreases in plasma sodium of up to 6 mmol/L occur during endurance rides in hot weather. The decreases are likely to result from significant sodium and water losses followed by partial replacement of the water deficit by drinking. Sodium concentrations may in fact increase in those animals that are not allowed to drink or that refuse to drink.

Potassium losses in sweat are also significant during prolonged exercise. Potassium is lost in sweat and is exchanged for sodium and lost into the gastrointestinal tract. During heavy exercise and sweating, muscle tissue is the major source of potassium replacement. Hypochloremia is observed commonly after endurance rides, reflecting chloride losses in sweat. Chloride is the major anion absorbed in the kidney, and in its absence bicarbonate is resorbed.

The most consistent acid-base alteration associated with endurance in hot environments is metabolic alkalosis, probably related to hypochloremia and hypokalemia caused by heavy sweating, and therefore may not be seen in cooler conditions. Hypocalcemia sometimes has been observed in endurance horses and might result from calcium losses in sweat or from disturbances of calcium homeostasis. These have been suggested to include energy deficiency, alkalosis, or competition with sodium and potassium exchange in the skeleton.

Even with frequent access to water, many endurance horses may develop clinical signs of slight to moderate dehydration during the course of a ride, as well as signs caused by some disturbance in electrolyte status. The combination of dehydration and sodium depletion results in a decreased plasma volume as determined by raised packed cell volume, total protein, and blood viscosityand in turn may result in inadequate tissue perfusion and inefficient oxygen and substrate transport, which can result in impaired renal function. Alterations in acid-base balance plus calcium, magnesium, and potassium depletion may contribute to the development of gastrointestinal tract stasis or ileus, as well as muscle cramps, synchronous diaphragmatic flutter, and rhabdomyolysis. If severe losses of water and electrolytes occur, then sweat production may decrease, resulting in even less effective thermoregulation.

Severe cases of dehydration coupled with electrolyte depletion may result in decreased renal perfusion and oliguria or anuria. Rhabdomyolysis may result from a combination of electrolyte depletion, poor perfusion, and resulting membrane instability. Myoglobinemia in human beings with decreased renal perfusion leads to kidney failure. Myoglobinemia is less common in the horse, possibly because metabolic alkalosis occurs more commonly than metabolic acidosis in heavily exercised horses. If volume depletion is severe enough, metabolic acidosis may occur in the horse because of anaerobic glycosis and may contribute to kidney failure in some horses.

9.9.1.1 Clinical Signs and Laboratory Findings

Box 9-5 shows some of the signs seen in exhausted horses and the associated laboratory findings. Signs may 489
last for several days. Various guidelines have been given in the literature to help distinguish the exhausted 490
horse from the nonexhausted, tired horse. The pulse and respiratory rates may be similar in both cases at the end of an endurance ride, but in the nonexhausted horse the rates tend to return to normal far quicker, for

example, to a heart rate of less than 60 to 70 beats per minute with a respiratory rate of less than 40 per minute within 25to 30 minutes, unless the ambient temperature is high. In the exhausted horse the pulse rate tends to remain greater than the respiratory rate, for example, greater than 70 beats per minute 30 minutes after exercise, with a persistently elevated rectal temperature.[126,188,201]

9.9.1.1.1

BOX 9-5 CLINICAL SIGNS AND LABORATORY FINDINGS IN THE EXHAUSTED HORSE

Clinical Signs*

Depression

Dehydration, anorexia, decreased thirst

Elevated respiratory and heart rates

Raised temperature

Poor sweating response

Poor jugular distention, increased CRT, decreased pulse pressure

Decreased intestinal sounds, laminitis

Muscle cramps

Synchronous diaphragmatic flutter

Laboratory Findings

Metabolic alkalosis

Paradoxical aciduria

Hypokalemia, hyponatremia, hypochloremia

Increase in CK, AST, LDH activities

Proteinuria

Azotemia

Lipidosis

Signs of hepatic failure

CRT, Capillary refill time; *CK*, creatine kinase; *AST*, aspartate aminotransferase; *LDH*, lactic dehydrogenase.

* Not all signs are present in all cases.

9.9.1.2 Treatment

Horses that appear depressed with persistently elevated heart and respiratory rates may respond to rest, cooling out, and access to salt, feed, and water. If one sees no improvement within 30 minutes, the horse often needs fluid therapy. In the more severe case of a horse that refuses to eat or drink, the horse needs prompt and vigorous fluid therapy. Fluids restore circulating blood volume, correct electrolyte deficits, and provide a source of readily metabolizable energy. One may administer fluids orally or intravenously. One can give 5 to 8 L orally every 30 minutes to 1 hour, if required, but one should stop if any discomfort or gastric reflux becomes apparent. One should avoid hypertonic solutions given orally. In severely affected animals, one can give up to 10 to20 L/hr of fluids intravenously; in addition, insertinga stomach tube may be necessary. One can use saline or Ringer's solution with potassium chloride added to provide approximately 10 mEq/L. After the horse starts eating hay, one may discontinue potassium supplementation. One can administer glucose as 5% dextrose saline, or one can add 50% dextrose to Ringer's solution to deliver between 50 and 100 g/hr (concurrent insulin administrationhas been recommended). Slow administration of calcium also may be of value. Sodium bicarbonate administration is not indicated, however, because acidosis, if present, resolves with fluid volume expansion and is contraindicated if the horse is in a state of metabolic alkalosis. The horse may require other therapeutic agents to control pain and anxiety, although one should use the NSAIDs and phenothiazine derivatives with extreme caution in the face of dehydration (low blood pressure) and possible renal dysfunction. Avoiding corticosteroid administration has been recommended unless absolutely necessary.

One can use cold water body sprays and alcohol baths, particularly over the head and neck region, to cool the patient. A common myth is that ice water bathing may lead to muscle cramps. However, whole body ice water bathing and cold water spray fans have been used successfullyin major international events under hot and humid conditions without adverse effects. In recumbent, hyperthermic patients, one should give cold water enemas delivered via a handheld gravity-feed rectal tube. Further information concerning exercise physiology under environmental conditions of high heat and humidity is available.[167,199–202]

9.9.1.3 Prevention

Many endurance competitors train their endurance horses to drink electrolyte-rich water. This may help partially to restore electrolyte concentrations in addition to water during a race. However, plain water always should be available as an alternative. The proper amount of water intake during competition is unknown because the maximum absorption of water from the gastrointestinal tract is unknown, considering that exercise draws circulation away from the intestine. The amount of water contained in the intestinal tract depends on the amount of fiber contained therein. Research is ongoing to determine the optimum combination and time of feeding of grains, forage, electrolyte supplements, and water before and during long-distance competition. These findings also vary depending on the type of competition (endurance versus Three-Day Event) and length of course (10, 50, or 100 miles). 490

491

Various suggestions have been made as to the optimal nature of any electrolyte supplement. Supplements containing from 1 to 4 times more sodium than potassium have been recommended. Sodium bicarbonate often has been suggested as part of an electrolyte mix, but because most endurance horses tend to become alkalotic, this in fact may be counterproductive and is not recommended. Additional sodium and potassium chloride supplementation for a few days after competition also may be helpful in replenishing body stores but often is unnecessary if the basic diet is acceptable.[200,201,203]

Many workers have reported beneficial effects from the oral or parenteral administration of vitamin E and selenium.[140,204] The beneficial effects of these compounds have been noted as often being difficult to assess because they often are given in addition to changesin diet and exercise.[205] Possibly any effect is caused by limitation/prevention of free radical–induced muscle damage. Oral administration is preferable to intermittent injection. The sections on equine motor neuron disease and white muscle disease give additional information concerning vitamin E and selenium deficiency.

9.9.2 ELECTROLYTE DEPLETION

Alterations in the intracellular or extracellular concentrations of electrolytes can occur in response to dietary deficiency and sweat losses or as a normal response to high-intensity exercise. The best way to assess the total body level of electrolytes is often to use fractional urinary excretions.[105,206,207] Table 9-2 lists recommendations for correcting abnormal dietary electrolytes. For example, in endurance exercise, horses may lose significant amounts of sodium, potassium, and chloride in sweat, which may contribute to fatigue, exertional rhabdomyolysis and synchronous diaphragmatic flutter. During anaerobic exercise, cellular acidosis occurs because of incomplete oxidation of pyruvate and the resulting accumulation of lactate. Volume depletion and poor circulation to muscle exacerbate acidosis. Systemic acidosis increases theserum fraction of ionized calcium and induces extrusion of potassium from muscle cells,[208] which may lead to changes in the action potential across the sarcolemma.

TABLE 9-2 Examples of Supplementation Given to 400- to 500-kg Horses Based on Fractional Electrolyte (FE) Excretion Test Results

FE VALUES	SUPPLEMENTATION
Low Na^+	2 oz (56 g)/day NaCl
Low Na^+ and K^+	2 oz (56 g) NaCl plus 10 oz (28 g) KCl/day for 2 weeks, then 2 oz (56 g) NaCl/day
High PO_4	Decrease bran intake if horse is fed, plus 2 oz (56 g) $CaCO_3$/day or alternative source(s) of calcium
High Na^+	Lower Na^+ intake (e.g., change source of hay if grown near the coast)
	Normal values: $FE_{Na}{}^+$ = 0.04–0.8; $FE_K{}^+$ = 35–80; FE_{PO4} = 0–0.2

Data from Harris P, Colles C: The use of creatine clearance ratios in the prevention of equine rhabdomyolysis: a report of four cases, *Equine Vet J* 20:459, 1988.

Aside from its role intracellularly in Mg^{2+} ATP, extracellular magnesium influences muscle cell function. Extracellular magnesium concentration is inversely proportional to acetylcholine concentration at the neuromuscular junction; therefore small changes in the serum concentration of magnesium reflect proportionately large shifts in whole body magnesium levels. Low blood levels of magnesium lead to increased membrane irritability and dysfunction of many enzymes necessary for protein, carbohydrate, and lipid metabolism. The most dramatic example of hypomagnesemia is grass tetany, which occurs in cattle grazing

magnesium-deficient pasture.[209] Whole body calcium balance is also important in muscular function, and hypocalcemia can be life threatening in most species. In horses, hypocalcemic tetany may be associated with heavy lactation, intestinal disorders, endurance exercise, and malnutrition.[210]

Sodium, chloride, potassium, calcium, and magnesium play key roles in muscle fiber contractility and irritability. Therefore small imbalances may lead to muscle dysfunction and possibly exertional rhabdomyolysis. Diagnosis of whole body electrolyte deficits can be difficult to confirm because of the rigorous homeostatic mechanisms in place that serve to maintain serum concentrations. Therefore a lack of correlation exists between intracellular ion concentrations and serum ion concentrations. In addition, electrolyte balance may shift in the body as a direct response to disease processes. For example, a whole body deficit of potassium may exist, but plasma potassium may be normal because of efflux of potassium from damaged or acidotic muscle.[65]

Kinslow, Harris, Gray, et al.[211] performed one study examining the role of total body electrolyte balanceand its effect on exertional rhabdomyolysis in 1995. The authors followed four mature Thoroughbred mares through their estrous cycles. Group mean percent fractional excretion of electrolytes in urine showed cyclical trends that appeared to fluctuate in relation to the stage of the estrous cycle. They saw large increases in the urinary excretion of sodium, calcium, and magnesium in samples collected during the period from 2 days preceding to 4 days following estrus. The authors found significant correlations in individual animals between low progesterone 491
concentrations and 24-hour fractional excretions of sodium, potassium, chloride, calcium, and phosphorus and 492
between serum estradiol 17β and calcium, magnesium, and chloride. These results suggest that ovarian steroid hormones may exert an influenceon urinary excretion of electrolytes in mares. Therefore estrous cycle–induced losses of sodium, calcium and magnesium in mares consuming a diet marginal or deficient in electrolytes could predispose them to exertional rhabdomyolysis.

To examine the effect of total body potassium on exertional rhabdomyolysis, Bain and Merritt[212] measured potassium concentrations within red blood cells and plasma in Thoroughbred horses with and without exertional rhabdomyolysis. The authors found that in fillies with exertional rhabdomyolysis, potassium concentration within red blood cells was lower than that of controls within 48 hours after an episode of exertional rhabdomyolysis. Whether decreased red blood cell potassium is an inciting cause of exertional rhabdomyolysis or results from exertional rhabdomyolysis is unknown. Beech and Lindborg[213] did not repeat these findings; they foundno difference in red blood cell potassium concentrationin horses with and without exertional rhabdomyolysis. However, the authors did find a significantly lower concentration of muscle potassium on a dry weight basis in horses with exertional rhabdomyolysis. Unfortunately, lower concentrations of muscle potassium did not correlate with the histologic appearance of the muscle. The authors concluded that low red blood cell potassium concentration may not be a valid indicator of reduced muscle potassium, and they did not associate potassium concentration with a predisposition for exertional rhabdomyolysis.

A study using potassium-depleted horses further clouds the role of potassium in exertional rhabdomyolysis.[214] In this study, the authors depleted healthy horses of potassium by withdrawing feed and by administering sodium bicarbonate and furosemide. The result was decreased plasma potassium (2.9 ± 0.3 mEq/L, treatment group; 3.3 ± 0.5 mEq/L, control), chloride, calcium, and magnesium compared with control horses. Red blood cell potassium concentration remained unchanged. A significant increase in CK activity occurred in the potassium-depleted horses compared with controls 240 minutes after exercise (296 ± 211 U/L, potassium depleted;86 ± 20 U/L, control). After exercise, three of the six horses developed diaphragmatic flutter, and two horses had CK activity beyond the normal range (685 U/L and 1374 U/L), and one horse was reported to walk with a stilted gait after exercise. The authors postulated that potassium depletion may play a role in exercise-induced muscle damage but could not conclude that it was the sole cause of increased serum CK activity. Unfortunately, a

similar study has not been performed in horses with underlying myopathies such as RER or PSSM to determine if potassium depletion influences rhabdomyolysis in a susceptible population.

Harris and Snow[215] also investigated the role of electrolyte imbalance in the pathophysiology of exertional rhabdomyolysis in 1991. The authors found that 100 of 144 Thoroughbred horses with exertional rhabdomyolysis had fractional excretions of electrolytes outside the normal range. Of those horses with abnormal fractional excretions, 72 of 100 responded favorably to additional electrolytes in their diet. However, the normal ranges for fractional excretions used in this study were more narrow than other published normal ranges, and other investigators have not duplicated the authors' results.[216] The intermittent nature of exertional rhabdomyolysis in racehorses also makes the verification of a real response to therapy difficult to confirm.

One must consider the relative concentration of electrolytes in the diet when examining their influence on exertional rhabdomyolysis. Poorly balanced electrolyte supplements may exacerbate dietary deficiencies of other ions. For example, high concentrations of serum potassium may aggravate the effects of low serum calcium, resulting in muscular hyperactivity.[217] Such increased levels of serum potassium are found during normal exercise. In 1998 Harris and Colles[218] described a case study that may support this theory. In this study, low dietary calcium and increased phosphate excretion were found in two of four horses experiencing exertional rhabdomyolysis. Urinary clearance ratios were low for potassium in one case and low for sodium in another. All horses were reported to improve with dietary changes, according to the investigators.

Electrolyte balance within the body and interactions between the major electrolytes play important roles in normal muscular function. In healthy horses, imbalances and deficiencies may occasionally cause muscular dysfunction. The fractional electrolyte test is the best test available to assess electrolyte state but must be applied and interpreted with care,[219] and the different feeding practices among countries may mean that electrolyte supplementation based on the fractional electrolytetest may have more or less relevance. In horses predisposed to exertional rhabdomyolysis, identical imbalances or deficiencies may lead to more severe rhabdomyolysis because of preexisting abnormalities in muscular function.

9.10 Horses With Altered Gait

Many abnormalities can affect the gait of horses. These problems may be related to musculoskeletal, cardiovascular, neurologic, or metabolic abnormalities. This section discusses muscle diseases that may result in altered gait as the presenting complaint. 492

493

9.10.1 ACUTE MUSCLE INJURY

9.10.1.1 Gastrocnemius Muscle Rupture

Rupture of the gastrocnemius muscle occurs in horses attempting to get up after a long period of recumbency (e.g., after anesthesia or postpartum paralysis). Rupture also occurs in animals that rear and fall over backward and occurs occasionally following overextension. In foals, ruptures have been reported following the first attempt of the foal to rise, especially if the foal has poor muscle tone or coordination. The condition also occurs in foals after an assisted delivery (dystocia) and in foals following manual attempts to straighten a fixed tibiotarsal joint. A rupture occurring in the tendon of insertion may result in avulsion of a portion of the tuber calcanei. If rupture occurs in the muscle belly, a hematoma may formand may calcify. The condition can occur unilaterally or bilaterally; however, the animal will be unable to standif rupture is bilateral or if complete

Achilles' tendon rupture occurs. The affected hock(s) may be flexed excessively because of the loss of the extensor influence of the gastrocnemius, giving the horse a squatting appearance. Heat, swelling, and pain are normally evident in the initial stages. The plasma muscle enzyme activities also tend to be elevated, at least initially.[220,221] Treatment involving support in a sling with the affected limb immobilized in an extended position has been recommended,[220] but the prognosis is guarded for a return to normal function.

9.10.1.2 Serratus Ventralis Rupture

Rupture of the serratus ventralis is rare and occurs as a consequence of dorsal impact trauma over the withers and neck region or after jumping a high fence or jumping off a raised platform. Animals usually are affected bilaterally. The thorax drops between the paired scapulae so that the dorsal borders are above the thoracic spinous processes. The croup is often higher than the withers. The condition is painful, and radiographs are needed to eliminate the possibility of dorsal spinous process fracture. The prognosis is poor. Recommended treatment is a prolonged period in a sling if the horse is suited temperamentally to such a restriction.[222]

9.10.1.3 Sore and Pulled Muscles

Pulled muscles (i.e., muscle tears or strains resulting in some disruption of muscle architecture and occasionally the formation of a hematoma) often are presented clinically during or immediately following exercise. Depending on the extent of the trauma and the muscle groups involved, obvious swelling and apparent pain on palpation may or may not be present. Plasma CK and AST activities may or may not be elevated significantly. Definitive diagnosis may be difficult, especially in chronic cases. Faradic stimulation, scintigraphy, thermography, and diagnostic ultrasound are some of the more common techniques used to diagnose a pulled muscle. Treatment tends to be a combination of rest and physiotherapy (e.g., manipulation, faradism, and ultrasound). Perhaps one should differentiate pulled muscles from the overexerted or sore muscle in which the associated damage tends to be at the cellular level involving structural damage of the contractile elements. Delayed onset muscular soreness (DOMS) is a commonly recognized condition in human beings. The soreness tends to increase in intensity over the initial 24 hours after exercise and peaks around 24 to 72 hours, hence its name. Whether DOMS occurs in the horse is not certain, although the diagnosis has been suggested when a stiff gait, palpable soreness, and a reluctance to move, as well as increased hydroxyproline concentrations, are observed 24 hours after exercise. Free radicals may be involved in the pathophysiology of acute and delayed onset postexercise muscular soreness. Treatment of DOMS in human beings varies from rest to light exercise with or without analgesia and the external application of heat. In the horse continued exercise may be contraindicated if the horse has experienced significant exertional rhabdomyolysis as diagnosed by moderate to high CK activity and in horses with an obvious muscle tear as indicated by the presence of heat, pain, swelling, and abnormal gait. In human beings the best prevention for DOMS is moderate daily increases in the degree of training.

9.10.2 CHRONIC MUSCLE INJURY: FIBROTIC MYOPATHY

Fibrotic myopathy tends to be a chronic, progressive disorder and may occur following excessive exercise over a long period of time that has resulted in the repeated tearing and stretching of muscle fibers.[59] Fibrotic myopathy also has been observed in Quarter Horses and stock horses following maneuvers such as sliding stops, in which the large thigh muscles are contracting while the stifle and hock are extending,[126,188] and in horses tied by a halter and shank and that pull back and fight strongly. Fibrotic myopathy also has been described as congenital, perhaps caused by periparturient trauma,[223] and following intramuscular injection.[224] The semitendinosus

muscle is affected most frequently, but adhesions to the semimembranosus and biceps femoris are common. Myopathy also may involve the gracilis or biceps brachii muscles.

The altered gait seen in horses with fibrotic myopathy of the hamstring muscles is characteristic. The horse walks with a shortened anterior phase of stride and then snaps the foot to the ground with a slap. The pathophysiologic process appears to involve trauma (external or work-related) followed by inflammation, muscle fiber atrophy, and replacement by fibrous tissue. Occasionally, mineral deposits form in the affected tissues, in which case the condition has been referred to as an ossifying myopathy.[224] The characteristic gait likely results 493
from a combination of scar tissue preventing normal extension and contraction of the muscle belly and possibly 494
an altered γ-efferent loop with an abnormal setting of the muscle spindle trigger, which may allow the early unchecked contraction of caudal thigh muscles during the late swing phase of the stride.[56]

9.10.2.1 Clinical Signs

Fibrotic myopathy has been described as a nonpainful mechanical lameness associated with a distinct gait abnormality. The condition can be unilateral or bilateral, and the horse pulls the affected limb(s) back and down before the end of the protraction phase so that the foot slams down, resulting in a louder sound on impact than that of an unaffected limb and in a shortened cranial or swing phase and a lengthened weight-bearing phase,[223] which has been referred to as a goose-stepping gait. The condition tends to be most obvious at the walk. If the condition involves the biceps brachii muscle, the horse shows a shortened cranial phase of the thoracic limb with a tendency for the foot to land at the toe in a way similar to those animals affected by navicular syndrome. Occasionally, one can identify the area of muscle damage because of a dimpling or depression in the skin overlying the muscle. In cases in which significant fibrous tissueor calcification of the muscle occurs, the site is readily palpable. The lameness tends to be unresponsive to routine antiinflammatory therapy.

9.10.2.2 Diagnosis

Diagnosis of fibrotic myopathy is based on clinical signs and history. In one report, two horses with congenital fibrotic myopathy did not have palpable thickening of the muscle or tendon and had no evidence of scar formation.[225] Histologically, one may observe a band of dense collagenous connective tissue or irregular, jagged pieces of mineral. Diagnostic ultrasound has been useful in some cases to confirm the diagnosis and to determine whether mineralization is present in addition to the fibrosis.

Fibrotic myopathy may be distinguished from stringhalt by closely observing the gait. In horses with stringhalt, the rear limb hyperflexes during the cranial or swing phase and a stepwise caudal jerking movement does not occur just before the foot hits the ground.[188]

9.10.2.3 Treatment and Prognosis

Surgical treatments described for fibrotic myopathy include resection of the fibrotic band, semitendinosus myotenectomy, and simplified semitendinosus tenotomy.[109,224,225] Some improvement in gait may occur in some horses after surgery, but complete absence of lameness is an unlikely result. Long-term prognosis is poor because the condition tends to recur after surgery. Postoperative problems with wound healing are common.[224] Transection of the semitendinosus tendon insertion on the tibia distal to the myotendonous junction has been said to resultin much less postoperative trauma, which may help to decrease the potential for recurrence,

[225] and full recovery has been reported anecdotally in a few cases. Performing a less radical excision and combining this with passive postoperative flexion-and-extension physiotherapy therefore may be preferable. Surgery is unlikely to be of value if the biceps brachii is involved.[224]

9.11 Disorders Characterized by Weakness

Disorders discussed in this section have in common a major clinical presentation of intermittent or continuous weakness. The major differential diagnoses for weakness include a variety of lower and upper motor neuron disorders. Hyperkalemic periodic paralysis, myotonia congenita, and myotonia dystrophica are characterized by an alteration in electric conduction across the muscle cell membrane. Equine motor neuron disease results from chronic vitamin E deficiency and consequential long-term oxidative stress. PSSM of Draft-breed horses may be characterized by progressive weakness and is discussed under the heading of disorders characterized by muscle cramping and elevated CK activity.

9.11.1 HYPERKALEMIC PERIODIC PARALYSIS

In human beings, three types of periodic paralysis are described: hypokalemic, hyperkalemic, and normokalemic. These disorders are caused by abnormalities in membrane permeability or a defective cation pump, resulting in an altered electrochemical gradient across the sarcolemma. The alteration in turn results in a change in resting membrane potential and threshold potential, resulting in a muscle fiber that is more or less excitable.[6] Together these disorders are classified as paramyotonias.

9.11.1.1 Clinical Signs and Laboratory Findings

In horses, hyperkalemic periodic paralysis (HYPP) occurs in Quarter Horses, Paint Horses, Appaloosas, and other horses carrying bloodlines that trace back to the sire Impressive. Affected horses tend to be well muscled. Because of this phenotype the defect has been postulated to confer or to be linked closely with other genes that are associated with a heavily muscled phenotype. Between episodes horses appear to be clinically normal and can be highly successful show horses.[226] In fact, many breeders believe that being a heterozygote greatly enhances the physique of horses and is therefore necessary to compete in the show ring. Scientific research confirming or refuting this has not been performed.

Prolapse of the membrana nictitans may be the initial sign at the onset of an episode of HYPP with or without 494
facial muscle spasm and generalized muscle tension. One may observe sustained contraction of the muscles of 495
the muzzle and drooling. Heart rate and respiratory rate are often normal or only slightly increased. Whole body sweating often has been reported. Muscle fasciculations are common, especially in the shoulders, flanks, and neck area. One may observe myotonia (sustained muscle contraction in response to percussion).[25,226,227] Although the horse may remain standing, it may not be able to lift its head and may show intermittent buckling at the knees and hocks. In mild cases, however, the only signs observed may be mild muscle fasciculations or twitching similarto signs of shivering. Recumbency may occur in some horses with diminished tendon reflexes, although affected animals tend to remain conscious and alert. Duration of episodes is usually short (20 minutes to 4 hours, typically 30 minutes to 1 hour). Death can occur during an episode, usually from cardiac arrest or respiratory failure.

Some horses demonstrate altered vocalization and audible respiratory stridor, which may indicate laryngeal spasm or paralysis.[228] In a survey of 69 homozygous horses, more than 90% were reported to suffer some

degree of abnormal airway noise, often between episodes, which tended to be an inspiratory stridor and was continuous in 21% of those evaluated. Exercise, excitement, and stress were possible triggering factors. Upper airway endoscopy of 24 horses revealed 9 with pharyngeal collapse, 10 with laryngeal spasm, 9 with pharyngeal edema, and 6 with a displaced soft palate. Clinically, homozygous affected animals tend to show exercise intolerance, whereas heterozygous animals may tolerate exercise well.[229]

In affected horses, one usually observes clinical episodes before 3 years of age.[230] However, a wide variation in clinical expression of the condition occurs (incomplete penetrance of the gene), with some affected animals showing minimal clinical signs. The variability in clinical signs may result from higher expression of mutant channels in the muscle of horses with symptoms than in those that are asymptomatic. Although variability in the severity of disease occurs between horses, in general, homozygous animals tend to have more severe clinical signs compared with heterozygotes. Muscle fiber diameter or fiber type is related to clinical expression. Management factors such as diet (high versus low potassium intake) and environmental stress may be more influential in the expression of the disorder.[229]

Between episodes, serum potassium concentration is usually within normal limits but may be increased slightly. During an episode, serum potassium concentration usually is increased (5.0 to 11.7 mmol/L),[231] although episodes without associated hyperkalemia have been reported.[232,233] Therefore the absence of hyperkalemia during an episode does not preclude a diagnosis of HYPP. Sodium and calcium concentrations may be decreased and hemoconcentration also may be observed during an episode. Serum CK and AST activities may be normal or mildly increased.[188,226,227] Recovery from an episode is associated with a decrease in serum potassium concentration.

Acute death from hyperkalemia-induced cardiac standstill may occur and is more likely in horses that are homozygous or poorly managed. Poor management may include feeding of diets high in potassium and irregular feeding, traveling, or strenuous exercise schedules.

9.11.1.2 Causes and Pathophysiology

HYPP in human beings is inherited as an autosomal dominant trait and has been studied extensively, as has paramyotonia congenita. To date, only HYPP has been diagnosed in horses, and the disorder also appears to be inherited as an autosomal dominant trait.[229,231] In human beings and horses, HYPP is characterized by intermittent attacks of weakness or paralysis, which are precipitated by a number of factors, including potassium intake, fasting, cold, and rest after exercise. Paramyotonia congenita typically presents as a cold-induced myotonia. Both conditions have been linked to the human adult skeletal muscle sodium gene on chromosome 17q. The genetic mutation responsible for HYPP in human beings affects a gene at the SCN4A locus that encodes the α-subunit of the adult human skeletal muscle voltage-dependent sodium channel.[235] In the horse the mutation is a phenylalanine to leucine mutation in the transmembrane domain IVS3 of the α-subunit of the sodium channel.[236] In affected individuals an increase in membrane sodium conductance occurs because of the defective subpopulation of the voltage-dependent sodium channels failing to inactivate and remaining open or repeatedly opening. A small rise in the serum potassium concentration because of clinical variation, ingestion of potassium, or muscular activity may trigger a further increase in membrane sodium conductance, depolarization of the muscle membrane, and movement of potassium out of the muscle cells. As the membrane depolarization develops, the membrane initially becomes hyperexcitable and shows myotonic behavior. With further depolarization of the muscle, the muscle cell membrane becomes unexcitable and paralysis occurs.[235,237] In Quarter Horses, all affected horses can trace their lineage to a stallion named

Impressive.[236,238] For this reason the disorder occasionally is referred to as Impressive disease. Whether the mutation in Impressive was a spontaneous mutation or was inherited is unknown. The mutation has become common in the Quarter Horse population because of the success of Impressive and his offspring in the show arena and the consequential extensive and long breeding career of Impressive. Of 20,000 plus samples collected between 1992 and 1995 approximately 63% were homozygous normal (N/N), 36%were 495
heterozygous affected (N/H), and 1% were homozygous affected (H/H).[229] These data translate to a gene- 496
positive frequency of 4.4% of the Quarter Horse population.

Plasma potassium concentrations of normal horses undergoing intensive exercise may reach the levels recorded during an episode of HYPP without any associated clinical signs,[105] which suggests that increased plasma potassium concentration alone is not responsible for the clinical signs.

9.11.1.3 Histologic and Muscular Characteristics

In human beings, periodic paralysis conditions sometimes are referred to as vacuolar myopathies. The vacuoles, visible on light microscopy, arise from coalescence of dilated components of sarcoplasmic reticulum, fusionof T-system networks, or focal fiber destruction.[239] In the horse, no abnormalities are found on light microscopy.[227,231]

Affected animals have a lower intracellular potassium concentration and a higher intracellular water volume than normal horses. Using whole-fiber intercostal muscle biopsies, the mean resting membrane potential of five affected horses was significantly closer to threshold potential compared with unaffected horses.[231] This may indicate a defect in membrane transport.

No difference is apparent between muscle fiber type distribution and fiber diameter between horses with HYPP and those without. However, the genetic defect may alter other less measurable muscle traits such as tone, which is why it appears that breeders and judges prefer affected horses over unaffected ones.

9.11.1.4 Electromyography

Numerous EMG abnormalities are apparent in HYPP horses at rest and during an episode.[231–233] Complex repetitive discharges are the most consistent abnormal finding, although one may observe myotonic potentials, fibrillation potentials, and positive sharp waves as well. The amount of abnormal spontaneous EMG activity can fluctuate substantially on repeated examinations.

9.11.1.5 Diagnosis

The most accurate way to confirm a diagnosis of HYPP is a genetic test using DNA extracted from equine hairor whole blood samples. The American Quarter Horse Association recognizes results of HYPP genetic tests that are performed through a licensed laboratory. The association can be contacted through their Web site at *http://www.aqha.com*. Tests are reported as homozygous normal (N/N), heterozygous (N/H), and homozygous affected (H/H). Before the development of the genetic test, a potassium challenge test was recommended to identify affected horses. This test has substantial potentially adverse affects and is no longer recommended. If a Quarter Horse dies acutely and one suspects HYPP, one may collect hair samples at postmortem for DNA testing. Increased potassium concentrations in aqueous humor samples support a diagnosis of hyperkalemia at the time of death.

Differential diagnoses for HYPP include other causes of collapse such as syncope, narcolepsy or cataplexy, and seizures, as well as other electrolyte disorders, neurologic dysfunction, and vitamin E– and selenium-responsive myopathy.[188]

9.11.1.6 Treatment

Recommended treatment for horses with acute episodes of HYPP varies depending on the severity of clinical signs. Mildly affected horses (i.e., nonrecumbent but with muscle fasciculations) may be exercised lightly. Caution is advised, because collapse is a potential risk in these horses. One may feed the horse a readily absorbable source of carbohydrate (oats or light Karo syrup) to promote insulin-induced reuptake of potassium. Acetazolamide at 3 mg/kg orally also may be beneficial. Such procedures often are undertaken routinely by responsible and experienced owners of affected animals.

During more severe episodes, especially when recumbency occurs, one may administer 5% dextrose with sodium bicarbonate (with or without insulin) to decrease serum potassium concentration. Slow intravenous administration of 23% calcium gluconate at 0.2 to 0.4 ml/kg diluted in 1 to 2 L of 5% dextrose (5% dextrose at 4.4 to 6.6 ml/kg) or bicarbonate at 1 to 2 mEq/kg have been recommended for treatment of acute, severe episodes of HYPP.[226,227,231,239] If required, one may administer potassium-free isotonic fluids.

Glucocorticoids may be contraindicated in susceptible horses because they induce episodes in human beings with similar disorders.[226] Inhalation of β-adrenergic agents has aborted acute attacks in human beings, but the use of such drugs has not been reported in HYPP-affected horses.[239,240]

9.11.1.7 Prognosis

In human beings with HYPP the prognosis for normal activity is considered good, although a permanent myopathy and weakness may occur. This also seems to be the case in the horse. In at least one horse the condition progressed, necessitating euthanasia.[226] A recent report suggested that “the chances of a paralytic episode occurring while the horse is being ridden appear unlikely. However, because episodes of paralysis are unpredictable, we recommend that only persons experienced with the symptomatology handle and ride affected horses and to use caution if any abnormal clinical signs are observed.”[229] Thousands of carrier horses are handled, ridden, and shown daily throughout the United States and elsewhere with little to no apparent danger to human beings. 496

497

9.11.1.8 Prevention

In horses, acetazolamide has been recommended as a daily medication to decrease the frequency and the severity of HYPP episodes. The recommended dose is 2 to 2.2 mg/kg orally every 12 hours for maintenance.[226,231] Hydrochlorothiazide also has been used.[227] One should feed affected horses oats or timothy hay rather than alfalfa, to decrease total potassium intake. Feeding grain 2 or more times a day, providing access to white salt (without potassium chloride added), and regular mild exercise also may be beneficial. One should establish a regular feeding and exercise schedule and should avoid rapid changes in diet, fasting, and water deprivation. Turnout to pasture or paddock may be beneficial.

In human beings, preventive therapy consists of frequent meals with a high carbohydrate content, avoidance of fasting or of exposure to cold or overexertion, and the use of diuretics such as acetazolamide or chlorothiazide, which promote potassium wasting in the urine. Small doses of albuterol, a β-adrenergic agent, also have been recommended in human beings.[240] Albuterol is believed to work by stimulating sodium and potassium ion pumps, enhancing potassium transport across the muscle cell membrane. Tocainide, a frequency-dependent antiarrhythmic drug, may prevent the weakness caused by the myotonia.[239]

Figure 9-6 Prominent muscle groups of the hindquarters and a knot of sustained muscular contraction following mechanical stimulation in a foal suffering from clinical myotonia.

9.11.2 MYOTONIA CONGENITA AND DYSTROPHICA

Like HYPP, myotonia congenita and myotonia dystrophica are characterized by abnormal electric conduction across the muscle cell membrane.[241,242] *Myotonia* is defined as the "delayed relaxation of skeletal muscle after a voluntary contraction or a contraction induced by an electric or mechanical stimulus."[8] Two forms of myotonia congenita are described in human beings, Thomsen's disease and Becker myotonia. Both result from chloride channel mutations. Thomsen's disease is inherited as a dominant autosomal trait; Becker myotonia is inherited as a recessive trait.[8,242]

In the horse, no membrane chloride defect has been identified. As in human beings, at least one form of the condition in horses persists in the face of neuromuscular blockade.[243,244] Only a few horses with myotonia have been described. Affected foals have a severely abnormal gait at birth and usually are euthanized. Because of the small number of affected horses described, whether myotonia in this species is heritable or results from spontaneous point mutations is unknown. To date, a complete description of clinical, histopathologic, and electrophysiologic findings in horses with myotonia congenita or myotonia dystrophica is not available.

9.11.2.1 Clinical Signs and Laboratory Findings

Stiffness of gait and prolonged contraction of affected muscle after local mechanical stimulation (finger flick) are the hallmarks of clinical myotonia (Figures 9-6, 9-7, and 9-8). Clinical presentation of horses with 497
myotonia varies.[188,245–249] One horse exhibited presence of myotonic discharges on EMG with no overt 498
primary muscular problems. This presentation is observed in Quarter Horses and does not appear to be progressive.

Figure 9-7 A young horse with myotonia. The heavy muscling of the hindquarters with atrophy of the distal limb and neck musculature are notable.

Figure 9-8 Prolonged myotonic discharges present on needle electromyographic examination. These high-frequency discharges sound much like a revving motorcycle but have no true waxing and waning. Instead the amplitude and frequency of the discharges change suddenly (as shown), altering the tone heard. Under general anethesia, suxamethonium or tubocurarine do not abolish these discharges.

A second myotonic syndrome in horses is characterized by early onset of progressive deterioration in muscle function. Signs are usually apparent within the first 6 months of life. Initially, lameness associated with stiffness and hypertrophy of the affected muscles may occur. The lack of fluid, smooth movement is most pronounced after rest and diminishes with exercise. In most affected horses the abnormality is confined to the hindquarters, although all four limbs may be involved.[249,250] No other body systems are affected. In many cases the horses become progressively weaker, although the clinical course may vary. On the basis of clinical, electrophysiologic, and pathologic findings,[246] this form of myotonia in horses has been suggested most to resemble human myotonia congenita or an undefined myotonia.[213]

A third, severe, and progressive form of myotonia reported in young horses is characterized by onset of clinical signs as early as 1 month of age.[249] Initially, horses exhibit generalized myotonia with hypertonicity of the larger proximal limb muscles, progressing rapidly to muscle stiffness, atrophy, and weakness. In one report, the authors also observed testicular hypoplasia, early cataract formation, and mild glucose intolerance, suggesting multisystemic involvement. This myotonic dystrophy–like disorder is associated with specific histologic changes.[213,249]

Serum CK and AST activities may be elevated in horses with myotonia, but these increases often are not sustained throughout the course of the disease and tend to be unpredictable.

Not all muscles that exhibit classic myotonic discharges (see the diagnosis section) show histologic changes. Fiber size variation, changes in number and size of the individual fiber types, increased numbers of central nuclei, and clustering together of fiber types with signs of necrosis and degeneration have been reported.[6,246,251] Differences in the histologic findings may reflect different forms of the condition.[246] Dystrophic changes and a normal distribution of fibers would be more likely in a diagnosis of myotonia dystrophica. In a muscle biopsy from a yearling horse with a likely diagnosis of myotonia congenita, histopathologic examination of the muscle revealed small anguloid atrophy of type 2A and 2B fibers. In addition, the muscle fibers in the biopsy were almost exclusively type 2B with fewer type 1 and 2A fibers. No evidence of central nuclei, muscle necrosis, or macrophage infiltration was apparent.

9.11.2.2 Diagnosis

The diagnosis of myotonia congenita or myotonia dystrophica is based on clinical signs, appropriate histopathologic changes in muscle, and the classic waning (dive-bomber) or waxing and waning (revving motorcycle) sounds of the EMG trains of high-frequency discharges (see Figure 9-8). These waveforms are visible on insertion of the EMG electrode and on voluntary, mechanical, or chemical stimulation of the affected muscle. Following percussion or stimulation, positive sharp waves and fibrillation potentials may be visible. These abnormal discharges ultimately subside when the muscle has been at complete rest for some time, although they can be initiated readily after the patient is given neuromuscular blockade (e.g., curarization).

9.11.2.3 Treatment

In human beings, quinine, procainamide, taurine, and phenytoin (diphenylhydantoin) have been recommended for treatment of myotonia. Most of these drugs decrease muscle excitability by blocking sodium movement.[237] The duration of EMG relaxation time after maximum voluntary effort is the only reliable indicator of muscle excitation and response to therapy in human beings[242] and is impractical in the horse.

Acepromazine, xylazine, thiopentone, pancuronium bromide, quinidine, and phenytoin have been used to treat horses with myotonia; however, significant improvement in clinical signs has not been observed.[151,252] Prolonged times to 90% muscle relaxation in vitro were observed in two horses with myotonia; these relaxation times were normalized by the administration of phenytoin to the affected horses. However, no obvious clinical improvement or significant effect on EMG was observed with the short duration of therapy. 498
[245] The long-term effectsof phenytoin on the clinical signs or progression of myotonia is unknown. The 499
prognosis for horses with any type of myotonia is poor; most affected horses are euthanized because of their inability to function as athletes.

9.11.3 EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a recently described disorder in horses characterized by neurologic and muscular dysfunction and muscle wasting. Initially the disorder was thought to have an inherited component or a specific geographic distribution.[253,254] Equine motor neuron disease now is accepted as being caused by chronic (6 to 24

months or more) vitamin E deficiency and has been reproduced experimentally.[255,256] Chronic vitamin E deficiency leads to chronic oxidative stress and resulting death of motor neurons and myopathy. Some horses manifest equine motor neuron disease as a primarily neurogenic disorder, and others have pathologic conditions of the muscles and nerves.

Clinically, affected horses present for various signs depending on the stage of the disease. Early complaints include weight loss and muscle atrophy (Figure 9-9). As the disease progresses, gait abnormalities become evident. The muscles of posture primarily are affected. The horse stands with a base-narrow stance, frequently shifts weight between legs and may stand with the tail elevated. This progresses to tremors when the horse stands still. At the walk or trot, the gait initially appears normal despite the return of tremors when the horse stands still. Some horses stand with the head low, apparently too weak to hold it in an elevated position. The penis may be partially prolapsed. Affected horses may progress to recumbency or may stabilize without further progression. Ocular manifestations include a characteristic fundic abnormality with a mosaic pattern of dark brown to yellow brown pigment deposited in the tapetal zone and a horizontal band of pigment at the junction of the tapetum and nontapetum. This abnormal pigmentation is associated with chronic oxidative injury resulting in lipid peroxidation of the retina.[253]

Figure 9-9 A horse with equine motor neuron disease. The generalized loss of muscle mass, the base-narrow stance, and raised tail head are notable.

Horses with equine motor neuron disease may have mild elevations in CK and AST activity. Complete blood counts are usually normal. Cerebrospinal fluid may have mild increases in protein and CK activity. Muscle biopsy may reveal neurogenic and myogenic atrophy.[257] Biopsy of the ventral branch of the accessory nerve reveals degeneration of the myelinated axon of the nerve and is present in acute and arrested cases. Muscle and

nerve biopsies may yield important information. Vitamin E levels in affected horses are significantly decreased (too low to read to 100 μg/dl; normal 400 μg/dl). Often multiple animals housed under identical conditions have similarly low vitamin E levels, but only one or a small number of horses may be demonstrating clinical signs. All horses should receive oral supplementation of vitamin E at 2000 to 4000 IU/day. Horses eating a vitamin E–deficient diet for many months have consistently low serum vitamin E concentrations that may take weeks to months to return to the normal range even with supplementation of the grass hay diet with commercial grains. Therefore top dressing commercial grain mixes with additional vitamin to provide 2000 to 4000 IU/day is recommended.

Horses displaying clinical signs at the time of diagnosis are unlikely to regain normal function. Once serum vitamin E levels are normal, aggressive vitamin E supplementation is no longer necessary. However, one should optimize daily intake to prevent future deficiency.

Low vitamin E intake is most common in horses eating hay and living without access to green pasture. Hay stored for long periods of time has less vitamin E than freshly cut hay. Many grain supplements have minimal quantities of vitamin E. Horses fed a grass hay diet without fresh pasture should have their vitamin E levels monitored and supplementation altered appropriately.

9.12 Disorders Characterizedby Muscle Wasting

Disorders characterized by muscle wasting or atrophy may be divided into two main categories, generalized and segmental. Generalized muscle wasting may occur in horses with equine motor neuron disease (discussed previously). Horses with streptococcal immune-mediated myositis often show a rapid onset of muscle wasting. A more insidious onset of loss of muscle mass occurs in horses with cachectic or disuse atrophy.

499

Horses with segmental atrophy may have atrophy arising from disuse, denervation (neurogenic atrophy), or fibrotic myopathy. These conditions are discussed elsewhere in this text. 500

9.12.1 STREPTOCOCCAL IMMUNE-MEDIATED MYOSITIS

Purpura hemorrhagica is an immune-mediated vasculitis associated with sensitization and cross-reactivity to proteins in the cell wall of *Streptococcus equi*. Purpura hemorrhagica in its most common form may be associated with mild muscular lesions following the vasculitis.[258] Skeletal muscle necrosis with fragmentation and swelling of muscle fibers and a cellular infiltration may be visible histologically. Classically, the lesions are believed to be caused by a type III hypersensitivity vasculitis.

Some bacteria may share similar immunodeterminants with muscle so that antibodies produced against the bacteria also affect the muscle directly, causing necrosis.[259] This type of purpura has myositis as its primary clinical sign rather than vasculitis. Two forms of immune-mediated myositis have been described in horses in association with *S. equi:* immunoglobulin G– and IgA-mediated. Both are less common complications of *S. equi* infection than purpura hemorrhagica.

IgG-mediated myositis in horses is characterized by rapid onset of muscle wasting (over days to 1 to 2 weeks) (Figure 9-10). The amount of muscle mass lost often is astounding considering the time frame. Horses typically have a history of clinical *S. equi* infection or live onfarms where infection is endemic. Muscle biopsy reveals inflammatory cell infiltration of the muscle and muscle cell atrophy. Horses are otherwise bright and alert and have a normal appetite. Blood and serum profiles are within normal limits with the exception of increased CK and AST activity. Globulin fractions may increase slightly. Horses respond favorably to a 4- to 8-week course of

corticosteroid therapy (dexamethasone and/or prednisolone). In horses in which one suspects an internal nidus of infection (abscess) as the cause of long-term exposure to the antigen, one should institute concurrent antibiotic therapy.

Figure 9-10 A horse with immunoglobulin G–mediated *Streptococcus equi* myositis. The profound atrophy of the lumbar muscles is notable. The horse responded well to a course of prednisolone therapy.

The IgA-mediated form of poststreptococcal myositis of horses is known as Henoch-Schönlein purpura and is a significantly more malignant form of myositis. Horses do not present for loss of muscle mass but may have residual loss of muscle mass should they survive. Affected horses have severe depression, muscle pain, stiff gait, thrombosis, and colic and may have areas of flocculent serosanguinous fluid several centimeters in diameter over the major muscle groups. Signs are progressive over the first 24 hours. In the first hours, blood analysis may show only a stress or endotoxic leukogram and high CK and AST activities. Physical examination and blood analysis progresses to support early disseminated intravascular coagulopathy and CK activities of greater than 100,000. Postmortem examination of these horses shows large areas of hemorrhagic necrosis within the large muscle groups (Figure 9-11). Histologic examination demonstrates myositis. Early aggressive cardiovascular support combined with large doses of dexamethasone is essential to attempt to treat these horses because mortality rates are high. If major vital organs are infarcted, the horse likely will not survive. However, with aggressive support and long-term steroid therapy (1 to 2 weeks at high doses, followed by a longer-term, declining dose regimen) the horse may survive. These horses often have pockets of *S. equi* infection internally 500
that may have been the nidus initiating the autoimmune reaction. Areas to be examined include the guttural 501

pouches and thoracic and abdominal cavities. Because these horses may have a nidus of infection, treatment also should include aggressive antibiotic therapy.

Figure 9-11 Muscle taken at postmortem from a horse with immunoglobulin A–mediated *Streptococcus equi* myositis. The sharp demarcation between normal and infarcted muscle is notable.

9.12.2 MUSCLE WASTING WITH MALIGNANT DISEASE/CACHECTIC ATROPHY

Because of a combination of cachexia, malnutrition, disuse, infection, and old age, muscle weakness and occasionally muscle necrosis may develop with malignancies involving other body systems.

9.12.3 ACUTE RHABDOMYOLYSIS, RECUMBENCY, SWOLLEN PAINFUL MUSCULATURE, AND DEATH

This section covers causes of acute rhabdomyolysis that may result in prolonged recumbency, systemic complications, or acute death that were not discussed previously. Of the conditions already discussed, horses with overexertion rhabdomyolysis; horses with underlying myopathies such as RER, PSSM, and EPSM; and horses with the IgA-mediated form of *S. equi* myositis may have episodes of rhabdomyolysis severe enough to cause recumbency or death. Neonatal forms of rhabdomyolysis, which are discussed in the following section, also may cause acute life-threatening rhabdomyolysis.

This section covers postanesthetic myositis, infectious forms of myositis, aortic-iliac thrombosis and toxic causes of rhabdomyolysis.

9.12.4 POSTANESTHETIC MYOSITIS

Postanesthetic muscle damage may occur in 6% of anesthetized horses.[260] Postanesthetic myopathy may be divided into two forms: localized (the more common form) and generalized.

9.12.4.1 Pathophysiology of LocalizedPostanesthetic Myositis

The localized form of postanesthetic myositis is likely a consequence of undergoing anesthesia combined with positioning the horse during the anesthesia with minimal padding (Figure 9-12). However, in some horses with adequate padding, recumbency results in direct pressure damage to the muscle or perfusion disturbances. Damage may occur because of increases in pressure within the osteofascial compartments, and a local ischemia. In this context, *compartment* is defined as a muscle or group of muscles enclosed within a low-compliance envelope of fascia and sometimes periosteum.[261] This definition is comparable to compartmental syndrome described in human beings and down cattle. Venous occlusion tends to result in a greater inflammatory response and more extensive fibrous tissue repair than arterial occlusion. Sufficiently high intramuscular pressures have been reported during anesthesia of horses to compromise capillary blood flow and possibly affect neural transmission.[261–264] Postanesthetic compartmental syndrome per se has been reported only rarely in the horse, perhaps because compartmental pressures decrease rapidly when a horse stands.[265]

Figure 9-12 A horse with postanesthetic myositis of the right gluteal muscles. The severe swelling is notable. The horse recovered fully with supportive care.

An increase in the lactate concentration of blood draining from dependent muscle, a significant postischemic hyperemia in dependent muscles, and increases in the plasma concentrations of thromboxane and prostaglandin E_2 have been reported in anesthetized horses. Damage may result from reperfusion of ischemic muscles rather than the ischemia itself. Reperfusion generates strong oxidants, possibly initiating membrane lipid peroxidation and muscle damage.[266]

Risk factors associated with postanesthetic myositis include the weight and fitness of the horse, positioning, padding, duration of anesthesia, blood pressure, and the type of drugs or anesthetic used.

In one study, researchers measured intramuscular pressure with a catheter in the lowermost limb of 11 laterally recumbent horses and observed the effect of position and padding. They found the highest pressure readings (up to 92 mm Hg) in muscles with no padding when the limb in contact with the table was kept perpendicular to the body and the free limb was unsupported. They measured the lowest pressure (11 mm Hg) with padding when the limb in contact with the table had been pulled forward and the free limb was supported.[263] They did not correlate muscle pressures with weight in this study, but animals with greater muscle mass appeared to have higher muscle pressures. Postanesthetic myositis has been reported in the upper limb as well 501
as the dependent limb. Therefore one should provide support for the upper limb. 502

Halothane anesthesia results in a decreased blood flow to muscle (0.40 ml/min/100 g muscle) compared with that seen in unanesthetized muscle (1.20 ml/min/100 g muscle).[267] A predisposition to ischemia may occur with certain disease states associated with underlying hypotension and a decrease in muscle perfusion. However, one study found no correlation between body weight, halothane vaporizer concentration, intracompartmental muscle pressures, cardiac output, blood pressure, and the development of postanesthetic forelimb lameness, although prolonging anesthetic time appeared to increase the degree or severity of lameness.[261] Since that study, two studies have looked at the effect of maintaining horses for a long time (3½ to 4 hours) under normotensive anesthesia (with a mean arterial blood pressure around 80 to 95 mm Hg) or hypotensive anesthesia, as a result of increasing the inspired halothane concentration (with a mean arterial blood pressure around 50 to 65 mm Hg). Hypotension, resulting from a high concentration of halothane, may predispose horses to postanesthetic myositis even when protective padding is used.[268,269] No increase in the incidence of problems is apparent when repeated episodes of normotensive anesthesia are undertaken, even with halothane use.[268]

Usually one observes clinical signs in the limb that is down (compressed) when in lateral recumbency. In the forelimbs, the triceps, deltoids, and occasionally the brachiocephalic and cranial pectoral muscles tend to be affected. In the hindlimbs, usually the biceps and vastus lateralis are affected. The flank muscles and masseter muscles also may be involved. Occasionally, however, the upper limb may be affected if its circulation is compromised. One study investigated the effect of limb position on cephalic venous pressure and triceps compartmental pressure in the upper limb of anesthetized normotensive ponies.[270] When the upper limb was in the position often used to allow surgical access to the lower limb (i.e., leg parallel to the floor and pulled back with reasonable force), considerably higher venous pressures were recorded compared with the limb in the neutral position (i.e., leg raised so that it was parallel to the floor and at right angles to the spine). The intracompartmental pressures were only found to be increased significantly when the upper limb was flexed horizontally, hard forward (i.e., with the leg parallel to the floor, fully flexed at the carpus, and pushed forward with reasonable force), which is a potential alternative leg position allowing surgical access to the lower limb. This position also resulted in significantly higher venous pressures than the neutral limb position, which suggests that this position is not advisable for clinical use. Impaired venous drainage may be a contributory

factor in the development of postanesthetic myositis, at least respecting the upper limb.[180] The position that appears to provide adequate surgical access to the lower limb with low compartmental and venous pressures is the flexed horizontal forward position (i.e., leg parallel to the floor, fully flexed at the carpus, and pushed gently forward).

When a horse is anesthetized in dorsal recumbency, the gluteal and occasionally the longissimus dorsi muscles tend to be affected. In one study, the adductor, pectineus, and gracilis muscles were involved, a finding attributed to arterial hypotension coupled with partial occlusion of the artery primarily supplying these muscles (the medial circumflex femoral artery), perhaps because of the hindlimbs being flexed passively.[271]

9.12.4.2 Clinical Signs

Clinical signs of postanesthetic myositis normally are seen during the initial recovery period but occasionally may be delayed for 1 hour or more. One first may suspect the condition if recovery is prolonged or the horse has repeated unsuccessful attempts to stand. Signs attributable to damage to one muscle group, one peripheral nerve, or mixtures of muscle groups and peripheral nerve(s) may be visible. Affected muscle groups tend to be hot andmay be swollen. The horse often resents palpation and usually is reluctant to bear weight on the affected limb. One may observe signs of severe pain with sweating. Classically, with forelimb muscle involvement, the affected animal stands as if the radial nerve has been paralyzed but can use the extensor muscles. If hindlimbs are involved, knuckling of the fetlock may occur; if the quadriceps femoris is involved, the stifle and hock may buckle and the animal may not be able to rise, especially if both hindlimbs are affected. Signs may persist for several days, even in uncomplicated cases.

In some horses, the only abnormality one may see is isolated, raised painful plaques, or one may find these along with forelimb or hindlimb dysfunction. These swellings usually occur over the table contact areas (hip, rib, or facial area) and may be caused by inadequate padding, trauma from positioning devices, or the weight of the patient.[269] Serum CK and AST activities increase in affected individuals, and one may observe myoglobinuria with significant muscle damage.

On occasion, after recovery from general anesthesia, a horse demonstrates considerable discomfort with continued treading of the feet, sweating, holding its limbs (usually the hindlimbs) in abnormal positions, and kicking out. The syndromes appear nonresponsive even to large doses of opioid and other analgesics, serum CK activities are not increased within the subsequent 48 to 96 hours, and no myoglobinuria is observable. These syndromes are assumed to be a form of paresthesia (pins and needles) caused by sensory neuropraxis, 502
but a strong clinical similarity to the condition of postanesthetic neuromyopathy is apparent. 503

9.12.4.3 Pathophysiology of Generalized Postanesthetic Myositis

The generalized form of postanesthetic myositis may be caused by a condition similar to malignant hyperthermia in human beings and swine. Alternatively, signs may appear during recovery, with many muscle groups affected independent of positioning.

The cause of generalized postanesthetic myositis in horses is uncertain but has been suggested to result from local ischemia that becomes more generalized because of hypotension, sensitivity of muscle cells to anesthetic drugs, or depolarizing muscle relaxants (suxamethonium), or a combination of these factors. In the two studies that looked at the effect of hypotensive anesthesia, cases of generalized myositis occurred during recovery.[268,269] In vitro examination of muscle using an adapted human contracture test (used for the identification of

malignant hyperthermia susceptibility) has shown increased sensitivity to caffeine and halothane in samples taken from certain susceptible equidae.[180] In this study the examined horse possibly had RER.

Whether horses with inherited myopathies are more or less prone to malignant hyperthermic events or postanesthetic rhabdomyolysis compared with the general horse population is unknown. Certainly, given the common nature of these disorders, one can be confident in saying that not every horse anesthetized that has an underlying myopathy has a malignant hyperthermic or postanesthetic rhabdomyolytic event. However, in human beings many different muscle disorders have been associated with an increased chance of malignant hyperthermic event when under general anesthesia. Therefore the potential exists, and inquiring whether a horse has a history of exertional rhabdomyolysis before performing general anesthesia is prudent. If a horse is believed to be at risk, premedicating that horse with dantrolene may be of benefit.

Generalized myositis may occur at any time during anesthesia. The temperature, heart rate, and respiratory rate increase, and muscles may fasciculate and contract. The horse may resist assisted ventilation and appear rigid. Death can occur.

Postoperative cases also tend to occur regardless of the length of the anesthesia and the positioning. Signs of extreme pain are apparent, and often the affected animal is unable to rise. The muscles may be rigid, and excessive sweating usually occurs. Signs of colic with myoglobinuria may be present, as well as fluid disturbances.

One may need to differentiate the condition from postanesthetic myelopathy, in which signs can range from difficulty in standing to paraplegia with flaccid paralysis and analgesia involving the pelvic limbs. In addition, loss of sensation and spinal reflexes over several contiguous segments may occur.

9.12.4.4 Laboratory Findings of Both Forms

Plasma and serum CK, AST, and LDH activities usually increase in both forms of postanesthetic myositis of horses. Increased plasma muscle enzyme activities may help differentiate those animals with overt muscular damage from those with conditions similar to paresthesia (possibly caused by a reduced blood supply to sensory nerve endings). Fluid and electrolyte disturbances also may be present. Hypocalcemia, hypomagnesemia, hyperphosphatemia, metabolic acidosis, hyperkalemia, and hyperglycemia have been reported and should be treated if present. Myoglobinuria may occur, and renal function may be compromised, necessitating treatment with intravenous fluids, furosemide, and dopamine. Muscle biopsy histologic examination is consistent with rhabdomyolysis.

9.12.4.5 Treatment

The aim of any treatment regimen is to relieve pain, prevent further damage, correct fluid and electrolyte disturbances, and maintain renal function. The added clinical manifestation in some cases is malignant hyperthermia in which muscle contractures cause a rapid increase in body temperature. The treatment usually recommended is similar to that for exertional rhabdomyolysis. If a metabolic acidosis is present, the horse may require intravenously administered sodium bicarbonate. If one recognizes the signs while the horse is anesthetized, one should stop using the anesthetic, whenever possible, and use alternative intravenous agents. If hyperthermia is present, the horse should be cooled rapidly and one should consider administration of fluids and dantrolene intravenously. Initial fluid infusion rates of up to 10 to 20 ml/kg/hour have been recommended, slowing to 4 to 5 ml/kg/hour. Analgesics that have been used include the NSAIDs and opioids. The effect of intravenously administered lidocaine in this scenario has not been evaluated. Diazepam and glyceryl

guaiacolate to reduce muscle spasm may be of value, but one should use them with caution because of possible ataxia and therefore increased problems with standing. The horse may require sedation if it is awake and anxious because of the pain. The α_2-agonists (xylazine, detomidine, romifidine) may provide good sedation and analgesia but may exacerbate ataxia; promote sweating, hypoinsulinemia, and hyperglycemia; and increased urine output, which may further exacerbate fluid loss. The vasoconstrictive effect of these agents together with their effect on cardiac output may compromise tissue blood flow further. Their use in the more violent cases may be necessary. Acetylpromazine in combination with opioids may provide good 503
sedation with minimal ataxia, and the vasodilatory effect may help improve tissue flow, provided circulatory 504
volume is maintained and hypovolemia does not occur.

Intravenously and then orally administered dantrolene sodium has been suggested to be beneficial.[181] Dantrolene at 1 mg/kg body mass orally has been used successfully to treat postoperative cases. However, recent work on the pharmacokinetics of dantrolene[180] has suggested that higher doses are likely to be needed to establish and maintain effective blood levels. An intragastric dose of 2.5 mg/kg every hour after a loading dose of10 mg/kg has been recommended.[181] Alternatively, an intravenous loading dose of 1.9 mg/kg has been suggested to achieve a more immediate therapeutic effect.[180] Dantrolene is not licensed for use in horses, is expensive, and is potentially hepatotoxic. Transient weakness and ataxia have been associated with intravenous administration.

9.12.4.6 Prevention

Correct positioning to prevent restriction of venous drainage or arterial input and the use of appropriate padding are recommended. Foam padding, for example, has been reported to be inferior to air mattresses or waterbeds.[272] Positioning is important, and various recommendations have been made: for example, one should elevate the upper limb and reduce pressure on the lower triceps by pulling the leg forward.[263] In lateral recumbency one should keep the hindlegs parallel or above parallel to the table and sufficiently separated to promote venous drainage. In dorsally recumbent horses, rather than letting the hindlimbs position themselves passively, one should provide support for them in slight extension by a hoist. Problems with hindlimb adductor myopathies do not always develop with passive positioning. One should avoid pulling back the hindlimbs. If one must draw back the hindlimbs in full extension, for example, for certain arthroscopic examinations, one should keep the surgical time to a minimum to reduce the risk of quadriceps myopathy. The flexed horizontal forward position, with the uppermost (noncompressed) forelimb parallel to the floor, fully flexed at the carpus, and pushed gently forward, is preferable when the surgeon needs access to the medial aspect of the lower carpus and distal radius.[270]

Withholding grain feed for 48 to 72 hours before general anesthesia may be beneficial. Heavily muscled, Draft-breed, and more athletically fit horses may be at an increased risk for postanesthetic myositis, in particular those with athletic-induced sports injuries. One should maintain blood pressure at more than 80 mm Hg (mean arterial blood pressure) to maintain muscle perfusion, should minimize halothane use, and may find intraoperative fluids and inotropes valuable.

Prophylactically administered dantrolene has been recommended, especially if the horse has a history of exercise-induced rhabdomyolysis or muscle problems following previous episodes of general anesthesia. Various doses have been used. In the United Kingdom, intragastric administration at 2 to 4 mg/kg has been recommended, whereas higher doses (10 mg/kg) have been used in the United States.[181] However, no

objective data exist to confirm the efficacy of prophylactic dantrolene administration for prevention of postanesthetic myositis in horses.

9.12.4.7 Prognosis

Prognosis depends partially on the extent of the muscle damage, the treatment instituted, and the temperament of the individual. Affected horses often recover completely, especially if the condition is localized to one muscle group. Occasionally, the horse may be left with residual muscle atrophy, fibrosis, and scarring. Death can occur with massive areas of ischemic myonecrosis and intrafascicular nerve fiber degeneration postmortem. Euthanasia may be required on humane grounds in horses that remain recumbent, have severe rhabdomyolysis, or that have uncontrollable pain. Further discussion of the pathophysiology, treatment, and prevention of anesthetic myoneuropathy is available.[*]

* References 68, 109, 126, 180, 181, 188, 271.

9.12.5 INFECTIOUS MYOSITIS

Infectious agents (bacteria, viruses, and parasites) can affect skeletal muscles. Some produce inflammatory reactions (myositis), whereas others give rise to often mild degenerative changes (i.e., myopathy). The differentiation can be difficult, especially in subacute and chronic cases, because an inflammatory reaction often induces secondary degenerative changes and vice versa.

9.12.5.1 Bacterial Gas Gangrene and Malignant Edema

Gas gangrene, malignant edema, and *clostridial myonecrosis* are terms used to describe infection of skeletal muscles with any of several *Clostridium* spp. organisms (*C. septicum, C. perfringens, C. novyi, C. sordellii*, and *C. chauvoei*). Germination of spores and vegetative growth occur when suitable local anaerobic conditions (alkaline pH, low oxidative reduction potential, etc.) exist following castration, parturition injuries, puncture wounds, and in particular, intramuscular injections.[273] Toxin production results in the destruction of the cellular defense mechanisms and significant tissue necrosis.

Affected animals may be found recumbent or dead. In less acute cases, lameness often occurs, which can be severe, or the horse is depressed. Painful muscular swellings may be present, and one may feel flocculation or 504
gas crepitation. The overlying skin initially may appear hot and be discolored but progress to become cool to 505
the touch, firm, and insensitive. Affected animals are often extremely depressed with systemic signs of profound toxemia. The prognosis is poor because the condition often progresses rapidly with ataxia, recumbency, coma, and death.

Diagnosis usually is made from the clinical signs and history. The finding of a nonclotting, malodorous fluid on needle aspiration (with or without gas) can be indicative of clostridial infection. Anaerobic culture, cytologic examination, and fluorescent antibody identification of the organism in tissue specimens have been recommended for a definitive diagnosis.[274]

Clinicopathologic changes tend to be nonspecificand similar to those seen in other septic-toxic conditions. Although increased serum muscle enzyme activities may be observable, they often do not appear to be in proportion to the degree of muscle damage.[274] In gas gangrene, extensive disintegration of muscle tissue tends

tooccur, with serosanguinous exudate and bubbles of gas. Malignant edema presents as a cellulitis with sparing of muscle fibers, although this may sometimes progress to gangrene.[37,274]

Treatment must be aggressive and typically includes initial administration of high doses of potassium penicillin G (44,000 IU/kg intravenously every 6 to8 hours) and surgical debridement. One may administer penicillin with metronidazole (20 to 25 mg/kg orally every 8 hours or 20 mg/kg intravenously every 8 to12 hours). Surgical debridement, fenestration, or both are essential to remove necrotic tissue and disrupt the anaerobic environment.[274] Long-term antibiotic and nursing care of the resulting wound usually are required. One should continue antibiotic therapy until infection has resolved and for a minimum of 7 days thereafter. In many instances, diffuse cellulitis extending down fascial planes occurs, necessitating therapy for at least several weeks. Supportive fluid therapy and analgesics are often necessary in the initial stages while signs of systemic toxemia are evident. One should use corticosteroidswith caution, although initial short-term therapy may be beneficial in horses with evidence of shock. Prognosis in most horses is poor.[273] Survival appears to be most frequent with *C. perfringens* infections, although extensive skin and muscle sloughing may occur, which in turnmay necessitate euthanasia.

9.12.5.2 *Sarcocystis*

Sarcocystis spp. are protozoal parasites that have an obligatory two-host life cycle. *Sarcocystis* spp. are found in horse muscle as part of the intermediate host infection. The horse consumes sporocysts with herbage that has been contaminated by carnivore feces (most commonly dog). Sporozoites are released and migrate to various sites. Second- or third-generation schizonts develop within muscle fibers as thin-walled cysts. Entry into muscle fibers can result in extensive fiber degeneration and significant enzyme release if a heavy infestation occurs. Enlargement of the cysts over the next 100 days orso can result in further muscle damage and lameness. Although three *Sarcocystis* species (*S. bertrami, S. equicanis,* and *S. fayeri*) have been recognized in horses, some controversy exists as to whether the three are distinct species.[37] In addition, whether the causative agent of equine protozoal myelitis, *S. neurona*, may affect skeletal muscle in the horse is unknown. A high postmortem prevalence of sarcocysts in muscle sections, occasional presence of sarcocysts in muscle biopsies, and evidence of transplacental infection have been reported,[275,276] suggesting that inapparent infection is probably common. A light and electron microscope study of sarcocysts in the horse has been described.[277]

Some dispute exists as to how heavy an infestation is necessary to cause clinical muscle disease in the horse. Twelve of 91 horses with a history of chronic muscle problems were positive for sarcocysts on muscle biopsy.[276] Separating the group of animals with sarcocysts from others on the basis of laboratory findings, history, or clinical signs was not possible. Weight loss, lethargy, difficulty in chewing and swallowing, generalized muscle weakness, and fasciculations have been reported in one horse with widely distributed sarcocysts, and clinical signs were attributed to the sarcocyst infestation.[278] Chronic illness in an experimentally infected pony also has been reported.[279] A heavy infestation is likely necessary to cause clinical disease.[280]

9.12.5.3 *Trichinella spiralis*

The nematode *Trichinella spiralis* may be found as an encysted larva in a bulging glassy segment of a muscle fiber in horses given feed containing contaminated porcine muscle tissue. Trichinosis therefore is rare. Usually one cyst per fiber is present, and the larva may be up to100 μm long. Degeneration (plus regeneration) may occur in neighboring muscle fibers. The larva can live for many years, but if the parasitized segment

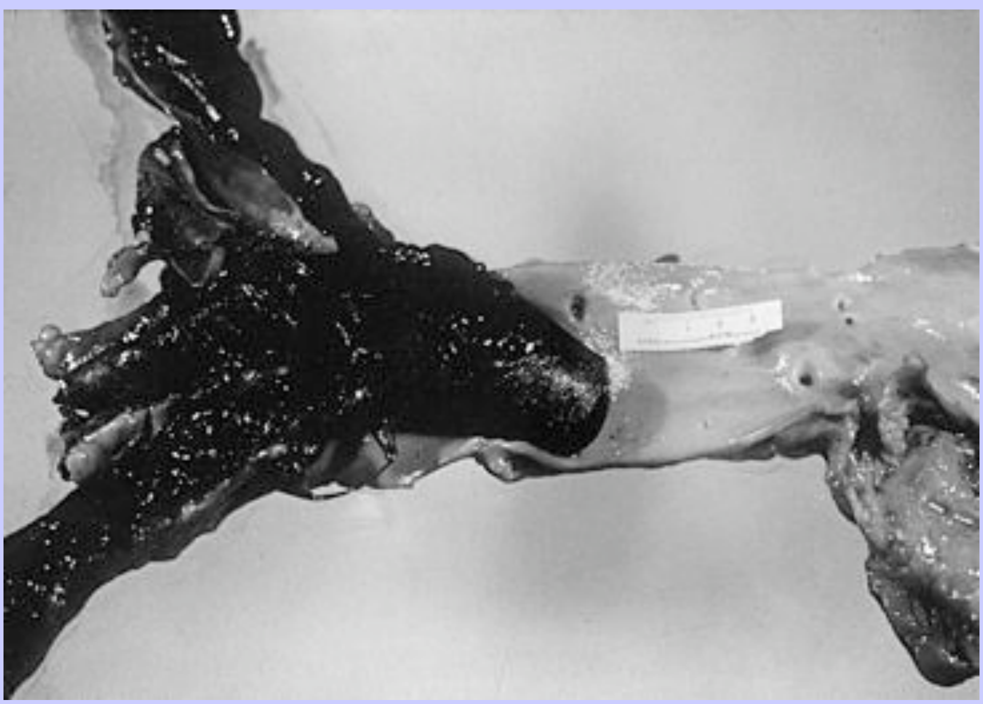
degenerates, the larva is exposed and soon dies. This in turn results in an acute, predominantly eosinophilic inflammation.[37,124] The parasitic infection appears to be asymptomatic.

9.12.6 AORTIC-ILIAC THROMBOSIS

9.12.6.1 Pathophysiology

Predisposing factors and causes of aortic-iliac thrombosis remain unclear.[281,282] Thrombi may result from damage to the vessel intima by migrating *Strongylus vulgaris* larvae. Signs of verminous arteritis in affected vessels (e.g., larvae, eosinophils, other inflammatory cells) have not been reported, however.[282] Larvae do not 505
tend to migrate as far caudally as the thrombi are found. The condition is apparently more common in 506
racehorses, which tend to be dewormed regularly. However, in horses not asked to perform maximally, the condition may not be clinically apparent and therefore may be underdiagnosed. An alternative suggestion is that *S. vulgaris* larvae could be an indirect cause of the condition via the formation of thromboemboli, which become organized and result in arterial occlusion and further thrombosis (Figure 9-13).[281,282] Hormonal, nutritional, and mechanical factors, as wellas prior infection with *Streptococcus equi* or equine influenza virus, have been proposed as predisposing factors to thrombus formation.[282–285]

Figure 9-13 Aortic-iliac thrombosis.



The internal iliac arteries are bound more closely to fascia than many other arteries. This, coupled with the large forces generated during movement, could increase the risk of injury to these vessels. In affected horses, plaques ascribed to intimal *S. vulgaris* migration have been reported in various branches of the abdominal aorta. However, similar thickenings also have been reportedin brachial, carotid, and cerebral arteries (sites in

which strongylus migrations are unlikely) in control and affected horses. Repair of spontaneous damage occurring to the arterial endothelium at areas of turbulence or arterial branching may result in plaque formation and eventually thrombus formation. One postulation therefore is that aortic-iliac thrombosis is similar to the human condition arteriosclerosis obliterans, a form of arteriosclerosis causing intermittent claudication.[282] Individual variation in the aortic quadrification or vascular repair mechanisms could explain why certain animals are predisposed to the development of this condition.

9.12.6.2 Clinical Signs and Laboratory Findings

Following exercise in affected animals, ischemia of the muscle usually occurs because of circulatory interference. The ischemia is usually reversible because the blood flow may be adequate when at rest or at light work. The clinical signs vary in severity according to the degree ofvascular occlusion, the vessels affected, and the extent of collateral circulation. The lameness tends to become more severe as exercise continues. Mild cases may be missed, however, because the horse appears normalwhen pulled up after a disappointing performance. Clinical signs may include poor performance, intermittent hindlimb lameness, transient lameness or weakness with exercise, a tendency to drag the toe and occasionally knuckling over, and gradual shortening of the stride leading to a transient inability to move. A peracute condition with paraplegia, shock, and death also has been recognized.

Hindlimbs may be affected, although usually one more than the other. After exercise the superficial veins on the more affected limb may appear collapsed (because of delayed filling) compared with the distended vessels on the more normal limb. The superficial veins of the affected limb(s) may take up to 90 seconds to fill after intense exercise compared with about10 seconds in normal horses. The affected limb often feels cooler than expected, especially around the gaskin, and may not sweat. One may feel a reduced digitalpulse. The animal may sweat profusely on the body, head, and neck and sometimes cow-kicks or shakes the affected limb (perhaps because of paraesthesias following reduced blood supply to sensory nerve endings). Full recovery tends to occur within 20 to 30 minutes. On palpation of the peripheral pulses at rest, one may detect abnormalities, including a flattened, weak, and prolonged contour to the pulse distal to the site of obstruction, whereas proximally the pulse may be normal or increased in strength. Alternatively, certain pulses may be absent.

Aortic-iliac thrombosis has been reported in males and females, although a greater incidence of clinical problems has been reported in males. One of the reasons for this difference in incidence may be a more efficient collateral circulation in females. The mean age of affected animals was 5.2 years in one study. Plasma and serum muscle enzyme activities are usually within normal limits before and after exercise. In severe cases with significant muscle damage, however, increases in CK have been reported.[282]

On postmortem examination, affected vessels tend to be enlarged and a large thrombotic mass usually is present at the aortic quadrification (see Figure 9-13) that may be attached to, and therefore possibly originate from, organized masses in the internal and external iliac arteries. These may extend to the bifurcation of the popliteal artery, but rarely do they extend far into the tibial arteries or the muscular branches of the femoral 506
artery. Histologically, affected muscles show signs of ischemia. Damaged fibers and supporting structures 507
tend to be removed with little sign of inflammation or fibrosis.[281]

9.12.6.3 Diagnosis

Diagnosis of aortic-iliac thrombosis is based on clinical signs and palpation of the thrombus per rectum or ultrasonic demonstration of the thrombus. In affected horses rectal examination often reveals no abnormality, with one easily missing signs such as a decreased arterial pulse or an unusual firmness of a vessel. The obstruction possibly may be fairly peripheral, which may in fact result in an increase in the pulse proximally. Ultrasonography is therefore the definitive method for diagnosis. A linear array ultrasound probe with a frequency of 5.0 or 7.5 MHz has been recommended.[285,286] Differential diagnoses include exertional rhabdomyolysis, cervical vertebral malformation, and degenerative joint disease of the tarsometatarsal joints. Perineural and intraarticular anesthesia help to eliminate lameness originating from the distal limb as a cause of rear limb pain.

9.12.6.4 Treatment

Treatment for aortic-iliac thrombosis aims toward elimination of the thrombus or development of collateral circulation. At present, an effective drug, selectively able to break down mature thrombi, is not available, and surgical intervention in the horse is difficult.

Sodium gluconate at 450 mg/kg body mass by slow intravenous infusion has been recommended to treat horses with aortic-iliac thrombosis,[287] but no evidence exists that the drug has any effect on a mature thrombus.[282] Prednisolone sodium succinate (100 mg 30 minutes before administration of sodium gluconate) mayhelp eliminate the systemic reactions frequently associated with this drug.[281,282] Other suggested protocols include monthly administration of ivermectin (Eqvalan, MSD-AGVET) and twice-daily oral doses of phenylbutazoneat 2.2 mg/kg body mass for 3 months.[285] However, improvement in treated horses may be due to the development over time of effective collateral circulation. Prognosis for horses severely affected with this condition is poor, and a hereditary predisposition has been suggested,[281] although little supporting evidence exists. Alternatively, horses may be treated conservatively with rest and administration of 60 grains of aspirin orally once daily.

9.13 Toxicoses

Only a few available and palatable toxic compounds cause muscle fiber degeneration in the horse. White snakeroot and *Cassia occidentalis* are the most common plants that may cause rhabdomyolysis. Ionophore contamination of feed also may lead to life-threatening rhabdomyolysis. For additional information, see Chapter 20.

9.13.1 WHITE SNAKEROOT

White snakeroot *(Eupatorium rugosum)* is a common plant in the central midwestern and northeastern United States. White snakeroot is a shade-loving plant growing well in damp, wooded areas, shaded river banks, and in steep canyons.[288] The toxic principle is tremetol, a fat-soluble high-molecular-weight alcohol, and plants may be toxic in fresh and dried forms. Clinical signs include progressive muscle tremors, weakness, choke, constipation, recumbency, arrhythmias, and death. Serum muscle enzyme activities increase significantly. At postmortem, one observes skeletal muscle necrosis and subepicardial and myocardial hemorrhages with grayish streaks in the myocardium.[289]

9.13.2 *CASSIA OCCIDENTALIS*

Cassia occidentalis (coffeeweed, senna) is toxic to horses and may cause ataxia, incoordination, recumbency, and death with liver and muscle damage. However, natural ingestion of this plant is uncommon.[290]

9.13.3 MISCELLANEOUS TOXICOSES

Selenium, iron, thallium, and perhaps sulfur and cobalt may cause muscle disease when fed at toxic levels. Metals such as iron may act by affecting vitamin E and selenium status or lipid peroxidation.[37] If ingested, bracken *(Pteridium aquilinum)*, horsetail *(Equisetum arvense)*, and rock fern *(Cheilanthes sieberi)* may induce a thiamine deficiency with signs of anorexia, gait disturbances, staggering, lack of coordination, lethargy, a weak and irregular pulse, and muscular tremors.[291]

9.13.4 IONOPHORE TOXICITY

9.13.4.1 Pathophysiology

Monensin, rumensin, and lasalocid are ionophores commonly fed as coccidiostats in food animals. Monensin is a carboxylic ionophorous antibiotic fermentation product derived from *Streptomyces cinnamonensis* and is used as a coccidiostat for poultry and as a feed additive for cattle because it increases feed utilization by altering rumen fermentation. Access to ruminant feed or accidental contamination of horse feed in a mill producing cattle and horse feed are the most common causes for intoxication.

The lipid-soluble monensin-sodium complex releases sodium in exchange for a proton after it crosses the cell membrane. The protonated monensin leaves the cell to pick up more sodium, and the cycle repeats. The increase in intracellular sodium concentration stimulates the sodium-potassium ATPase pump and indirectly results in an increase in calcium. This increase in intracellular calcium then may result in the release of certain factors such as catecholamines, which in turn may be responsible for some of the clinical signs seen, 507
especially in relation to the heart. When mitochondria become saturated with calcium, the process of oxidative 508
phosphorylation is disturbed and supplies of ATP decrease. Swelling and disruption of mitochondria follows, resulting in release of stored calcium, which may potentiate or precipitate catecholamine-induced cardiac arrhythmias. Increased intracellular calcium concentrations also may result in a brief period of extreme contraction of muscle (because of effects on actin-myosin binding) as well as release of various cellular lytic enzymes. The rapid onset of cardiac or skeletal muscle necrosis may result from energy deficiency resulting from these lytic processes. Small concentrations of monensin also may result in an increase in intracellular potassium concentration; large concentrations of monensin tend to decrease intracellular potassium concentration. Other tissues less dependent on ATP may not show such severe signs.[124,292,293] In muscle, swelling and disintegration of mitochondria are the first visible lesions, although monensin does not cause mitochondrial structural defects in cultured muscle cells.[294] Further work is needed to determine if other substances or metabolites of monensin are involved in pathophysiology of toxicity in vivo.[292]

9.13.4.2
Clinical Signs

Horses are sensitive to monensin. Signs of toxicity may be apparent after ingestion of 2 to 3 mg/kg body mass of crystalline monensin (compared with 20 to 34 mg/kg for cattle). (The median lethal dose for mycelial monensin is estimated to be 1.38 ± 0.19 mg/kg body mass.) The increased susceptibility of horses to monensin toxicity may be because horses do not clear monensin from the bloodstream as rapidly as cattle. In addition, equine heart muscle is sensitive to the effects of catecholamines.[292] Following ingestion of a single toxic dose, signs of lethargy, muscular weakness, and stiffness, often with recumbency, occur within 24 hours. In the early stages, progressive hypokalemia resulting in cardiac conduction disturbances occurs.[293] Cardiovascular signs may include tachycardia with possible arrhythmias, prominent jugular pulse, congested or pale mucous membranes, cold extremities, weak pulse, and profuse sweating. Tachypnea, hyperpnea, or dyspnea may be apparent. Early on, affected animals may show signs of colic, including sweating, increased pulse, and increased or absent borborygmus. Amounts of feces may be reduced, or no feces may be passed. Animals may be anorectic. Myoglobinuria and muscle tremor also may be apparent, together with progressive ataxia and signs of central nervous system malfunction. Depending on the dose ingested (and the individual), death may occur within 24 hours. Hindlimb muscles tend to be involved most severely.[37,124,292] Progressive cardiac insufficiency, weight loss, and sometimes renal failure are more common with chronic toxicity in the weeks following a single, lower dose exposure. In such cases, clinical signs related to skeletal muscle involvement may disappear, although poor performance and muscular weakness may be apparent if the horse is asked to perform. Signs of chronic toxicity may not be noticed for weeks after ingestion of the compound has stopped.[295] Monensin-containing feeds are often unpalatable, and owners may recollect a "bad" bag or shipment of feed that some horses refused to eat in the recent past.

9.13.4.3
Laboratory Findings

In peracute cases, in which the horse dies within 24 hours, a progressive hemoconcentration associated with increased urine output and decreased urine specific gravity occurs, together with increased blood urea nitrogen and creatinine concentrations.[293]

Serum CK and AST activities may be elevated moderately to significantly, primarily because of skeletal muscle damage. The increase in total LDH activity appears (at least initially) to be caused by LDH_1 and LDH_2 isoenzymes and may be related to increased erythrocyte fragility and hemolysis. Increases in alkaline phosphatase activity also have been observed, apparently from an increase in the bone isoenzyme.[293] Hemoglobinuria, myoglobinuria, or both may occur.

Sodium concentrations do not change greatly. Serum calcium concentration tends to decrease initially, within the first 12 to 24 hours, by about 10% to 15% and then recovers. Hypokalemia tends to occur in the first 24 hours with a decrease of 1 to 2 mmol/L followed by a return to normal by 36 hours. In chronic toxicity, clinical findings are often nonspecific and reflect the various organs involved. In one study of 32 horses with a history of unthriftiness and poor performance following prior ingestion of monensin-contaminated feed, the authors observed decreased serum bilirubin concentration and increased alkaline phosphatase activity. In four horses, they also observed increased LDH_5 activity.[295]

In horses that die peracutely, one may not observe gross lesions and may rely on feed analysis for diagnosis. In less acute cases, the gross changes are not pathognomonic for monensin toxicosis and can include edema,

hydropericardium, hydrothorax, ascites, hemorrhages, and pale areas in the heart or diaphragm.[292,294,295] Differentiating this condition histologically from vitamin E and selenium deficiency or exertional rhabdomyolysis may be difficult.[37] However, history of feed problems, signs in multiple horses, and evidence of heart failure in chronic cases aids in diagnosis.

9.13.4.4 Diagnosis

The clinical signs and history of access to monensinare important in the diagnosis. The finding of high monensin concentrations in feed and stomach contents may confirm the diagnosis. The ingestion of blister 508
beetles (*Epicauta* spp.) can cause cardiomyopathy, and one should exclude this from the differential diagnosis 509
along with white snakeroot toxicosis.

9.13.4.5 Treatment and Prognosis

In acute monensin toxicosis, intensive isotonic polyionic fluid therapy with additional potassium has been recommended for treatment. Although this may support the horse during the initial crisis, prognosis is guarded because longer-term actions of monensin, particularly on the heart, still may cause death.[293,295] Activated charcoal or mineral oil administered orally may help to decrease further monensin absorption. One should avoid purgatives that act by stimulating the vagal system because of the risk of causing arrhythmias in an already damaged heart. Similarly, intravenously administered calcium may not be advisable. One should avoid cardiac glycosides because they may work synergistically with monensin, resulting in extensive cardiac muscle damage. Horses that have clinical signs of heart failure after previous exposure have a poor prognosis for long-term survival.

9.14 Muscle Disorders of the Neonate

9.14.1 NUTRITIONAL MYODEGENERATION/WHITE MUSCLE DISEASE

Vitamin E or selenium deficiency and the resulting muscle disorder often are described in the literature as a muscular dystrophy. The term is inappropriate considering that *muscular dystrophy* is defined in human medicine as a group of progressive genetically determined primary myopathies. They usually are not present at birth, and neural and vascular components are not involved initially. Regeneration of muscle cells is absent or inadequate, and replacement of muscle cells with fat and fibrous tissue occurs. This differs from the nutritionally associated disease in horses, which therefore should not be called a muscular dystrophy.

9.14.1.1 Clinical Signs and Laboratory Findings

Clinical signs and laboratory findings in horses with nutritional myodegeneration vary depending on distribution of the muscular lesions and the extent of damage. Signs are seen most commonly in animals less than2 months of age and can occur peracutely and progress rapidly. Box 9-6 lists differential diagnoses for nutritional myodegeneration. Death may occur immediately from a fatal arrhythmia, or after a few hours from exhaustion and circulatory collapse. The myocardium, diaphragm, and respiratory muscles usually are involved, leading to heart failure, dyspnea, and pulmonary edema. Occasionally, one may find painful subcutaneous swellings in particular over the rump, ventral abdominal wall, and nuchal crest. These swellings

are more common in older foals. In older animals, sudden postexercise recumbency may occur with death within a few hours caused by pulmonary edema and myocardial failure.[188]

9.14.1.1.1

BOX 9-6 DIFFERENTIAL DIAGNOSIS OF NUTRITIONALLY RELATED MYODEGENERATION

Atypical myoglobinuria

Botulism

Cerebellar diseases

Colic

Equine motor neuron disease

Equine rhabdomyolysis syndrome

Medullary diseases such as herpesvirus type 1 and myelitis

Muscular dystrophy

Polymyositis

Purpura hemorrhagica

Rabies

Septic polyarthritis

Spinal cord diseases

Suppurative meningitis

Tetanus

Tick paralysis

Trauma

Various causes of dysphagia (e.g., cleft palate, ulcers, and peripheral damage to certain cranial nerves)

Various causes of dyspnea (e.g., pneumonia and cardiac disease)

In less acute cases, weakness, stiffness, and lethargy are common findings. The body temperature can vary from subnormal to supranormal. The affected horse may become recumbent and unable to rise. Hindlimb muscles often appear to be sore on palpation. Dysphagia is often the first sign noted because of involvement of the tongue and pharyngeal and sometimes masticatory muscles and often contributes to the development of aspiration pneumonia. Regurgitation, starvation, and ptyalism are other possible complications. If the heart is involved, one also may find tachycardia, arrhythmias, systolic murmurs, and respiratory distress. Myoglobinuria has been reported in a number of cases. A swollen tongue and tachypnea are unusual

presenting signs. A 10-month-old aborted fetus with histologic lesions typical of this condition has been reported.[152]

The condition appears to occur in any breed and does not appear to have a sex predilection. Recovery can occur within days or weeks of the presenting signs.[152] Signs may occur in an individual animal or several animals within a group.

In the acute form, AST and CK activities are elevated. In the recovery stages the values may be increased only 509
slightly or within the normal range. Increased CK and AST activities also have been found in about 25% of 510
the mares of affected foals and in 20% of clinically normal foals in the same stables.[296] This finding was suggested to reflect the existence of subclinical lesions in these animals.

Because selenium is incorporated into erythrocytes only during erythropoiesis, the GSHPx activity of red blood cells may be a better indicator of long-term selenium status than serum selenium values (although GSHPx values plateau at high selenium intakes, i.e., when blood selenium levels of approximately 0.12 μg/ml serum or 0.16 μg/ml whole blood are reached). Low GSHPx, selenium, and vitamin E values have been reported in affected animals. In the author's laboratory, for example, GSHPx values of greater than 30 IU/ml of red blood cells would be expected in stabled animals fed a balanced diet. Values greater than 25 IU/ml may be expected in grazing animals on an adequate intake; values less than 20 IU/ml are associated with animals with deficient dietary intake. Serum vitamin E concentrations of at least 400 μg/dl are considered normal. Concentrations between 200 and 400 μg/dl are considered marginal, and below 200 μg/dl suggests deficiency. Reference values vary according to the laboratory. One should take care with collection of samples, especially for vitamin E determination, because contact with rubber may interfere with analysis. One cannot use single-serum sample assays as an indicator of vitamin E status in individual horses because of high variability in values between animals and within the same animal.[297] Normal vitamin E concentrations have been reported in some affected foals, possibly reflecting recent ingestion of colostrums. Many of the dams of these foals had low serum vitamin E concentrations (<200 μg/dl), and possibly the selenium levels of affected foald were low before suckling. The liver plays a role in selenium storage, and liver selenium concentrations of three foals (119 ± 5 μg/kg) were statistically lower than those of foals with other diseases (162 ± 20 μg/kg).[296] Liver selenium concentrations on a wet weight basis have been reported to be adequate at 0.300 to 1.000 ppm, marginal at 0.161 to 0.299 ppm, and deficient at 0.160 ppm or less.[298]

Acetate electrophoresis confirmed myoglobinuria in one horse.[152] In other horses the diagnosis of myoglobinuria was made visually or via a positive reaction to orthotoluidine agent in a test strip. Hyperlipemia has been reported in some horses with and without signs of steatitis post mortem.[37,150]

Electrolyte disturbances include hyperkalemia, hyponatremia, and hypochloremia. Such findings may be associated with a poorer prognosis. Metabolic acidosis may be present, and the concentration of blood urea nitrogen often is increased; this may be due at least in part to prerenal factors. One may observe alterations in the hemogram depending on the presence or absence of complications such as aspiration pneumonia.

In foals with evidence of nutritional myodegeneration, a full hematologic and clinical chemistry profile with a urinalysis is advisable. In very young foals, especially those with dysphagia or poor sucking reflex, checking IgG concentrations also is advisable.

9.14.1.2 Postmortem Findings

Postmortem examination of neonatal foals with peracute white muscle disease often reveals few macroscopic lesions. In acute cases, muscle may appear pale and streaks may be present representing areas of coagulative necrosis next to less affected tissue. All muscle groups of the pelvicand thoracic limbs commonly are affected. The muscles of mastication, diaphragm, tongue, pharynx, and cervical musculature also commonly are involved. Distribution of lesions is usually bilateral and symmetric. In subacute cases, one may observe yellow-white streaks in the heart and muscle, representing calcification.[157] Steatitis, yellow fat deposits, and fat necrosis also have been described in some but not all cases.[152]

9.14.1.3 Histologic Findings

Typical histologic findings observed at various stages of nutritional myodegeneration have been described.[157] During the first few days, extensive floccular, granular, and severe hyaline degeneration of myofibers occurs. After about a week, phagocytosis of necrotic tissue occurs with endomysial thickening caused by edema, mononuclear infiltration, and proliferation of fibroblasts. By 2 weeks, epimyseal connective tissue has proliferated. Early regenerating fibers coexist with signs of myodegeneration.

9.14.1.4 Diagnosis

At present, diagnosis of nutritional myodegeneration is based on the following:

1. Appropriate clinical signs
2. Increased serum AST and CK activities, especially in the acute stages
3. Decreased blood selenium and GSHPx values
4. Response to vitamin E and selenium administration

The list of differential diagnoses (see Box 9-6) may be extensive, depending on the signs in the affected animal. However, few of the conditions listed in Box 9-6 result in significant increases in muscle enzyme activity or myoglobinuria. Differentiating this condition from colic is important.[150] Foals with botulism usually have decreased muscle tone.

9.14.1.5 Treatment

Reduction of physical activity and prompt administration of vitamin E and selenium usually are 510
recommended. Injections of vitamin E and selenium usually are required, but because of the potential for 511
anaphylactoid reactions, one should avoid the intravenous route. One should give deep intramuscular injections, although one should note that intramuscular injections may give rise to muscle soreness and have been associated with abscess formation. Therefore one should take care regarding possible toxicity.[295] Aggressive daily oral supplementation of vitamin E coupled with a single intramuscular injection of selenium may be the best route of therapy, because many commercially available selenium/vitamin E combination injectable preparations actually contain little vitamin E. The selenium injection may be repeated in 3 to 7 days if necessary. Nasogastric feeding is preferable in dysphagic, anorectic, or recumbent foals.[298] The foal often

needs fluid therapy to combat dehydration and electrolyte disturbances and to maintain urine output and prevent myoglobin-associated renal damage. One should not use fluids with high potassium content when hyperkalemia is present, although one should take care after the animal has been rehydrated and its acid-base status restored to ensure that hypokalemia does not occur, especially if the horse is dysphagic.

Antiinflammatory agents may be helpful to reduce pain and swelling but should be used with caution in foals because of their ulcerogenic properties. Antibiotic therapy may be advisable if the animal is dysphagic or shows signs of respiratory distress or pneumonia. Selenium deficiency by itself may result in immunosuppression,[298] which may be compounded by complete or partial failure of passive transfer.

9.14.1.6 Prevention

Feeding pregnant mares an adequate level of nutrition including adequate amounts of vitamin E and selenium is imperative. Although whether the status of the mareat delivery has a significant influence on the reserves of these compounds in foals is unproven, nutritionalstatus of the mare is likely at least one importantfactor. Certainly the vitamin E status of the mare has an influence on the likelihood that the foal may develop equine degenerative myelopathy, a neurologic disorder. Therefore vitamin E status may influence the development of white muscle disease as well. In herds or areas where horses are known to be deficient in either compound, supplementation of the foal is recommended. Feeding a constant daily level is preferrable because injectable preparations have been associated with fatalities.

Recommendations for supplementation of vitamin E range from 1.5 to 4.4 mg/kg α-tocopherol acetate daily for adult Standardbred horses on a low vitamin E diet.[299] A least eight different tocopherols with vitamin E activity exist. α-Tocopherol has the greatest activity andaccounts for 70% to 90% of total biologic activity. The supplementary form of vitamin E is usually α-tocopherol acetate, which is not an antioxidant and is therefore much more stable in moisture, heat, and oxygen. α-Tocopherol acetate is converted to active tocopherol during digestion and absorption from the gut. Adding 5 mg of additional vitamin E for every 1% of blended fat has been recommended and may be important for endurance horses. The value of vitamin E injections has been questioned, especially because the amounts within the injectable preparations are low.[152] Feeding good-quality, properly stored hay and grain and allowing access to good-quality green forage may help to maintain vitamin E intake.

Feeding 1 mg/day of selenium maintains blood selenium values above the level associated with myodegeneration in horses and foals.[300] Only limited amounts of selenium cross the placenta, which may explain why clinical cases may occur in offspring of supplemented mares.[301] The milk from mares that have been supplemented appears to contain more selenium than milk from unsupplemented animals, but the amount present is small because selenium is not concentrated in milk. Organic selenium supplementation appears to be more beneficial than inorganic. Therefore although many recommend, especially in deficient areas, that mares be supplemented from late gestation through lactation, others prefer to supplement the foals at birth, 2 weeks, and 6 weeks later,[152,300] although this may not prevent the cases seen at birth or in the first few days of life. Others recommend that, in problem areas, a selenium injection be given at birth and then every 2 to 3 months during the first6 months of life.[126] Still others recommend injections of selenium every 5 to 10 days.[298]

In pigs, selenium has been suggested possibly to be teratogenic. Teratogenesis has not been observed in mares, but one recommendation is that selenium injections not be given early in a pregnancy. The levels recommended for oral supplementation of mares during pregnancy have varied from allowing free access to a trace mineralized salt containing 15 to 30 ppm selenium or feeding a ration containing 0.5 ppm selenium (on a

dry matter basis). Alternatively, feeding at a higher level (0.1 to 0.2 ppm), equivalent to the 1 mg/day mentioned earlier, has been recommended.[298] One must take special care with selenium administration because toxicity can occur. The single minimum lethal dose of oral sodium selenite is 3.3 mg/kg in the adult horse and results in a variety of clinical signs including severe dyspnea, incoordination, diarrhea, recumbency, and death within a few hours. One should not expect increases in GSHPx activity in the blood until 2 to 3 weeks after selenium supplementation. GSHPx values tend to plateau before toxic levels of selenium are reached, and several months may pass before levels decrease following cessation of supplementation. 511

512

9.14.1.7 Prognosis

The prognosis for foals with nutritional myodegeneration is guarded, especially if the foal is recumbent or dysphagic or if treatment has been delayed. Prognosis also seems to be less favorable in animals with acid-base and electrolyte disturbances.

9.14.2 RHABDOMYOLYSIS

Acute rhabdomyolysis in neonates hospitalized for prematurity, sepsis, and failure of passive transfer has been reported.[302] Rhabdomyolysis developed after 1 to 6 days of hospitalization and was accompanied by profound hyperkalemia, hyponatremia, hypocalcemia, and hyperphosphatemia. Analysis confirmed that affected foals had low selenium and/or vitamin E status at the time rhabdomyolysis was noted. Whether selenium and vitamin E status was normal or marginal at birth and oxidant stress related to sepsis led to rhabdomyolysis or if animals were born with deficient reserves of selenium or vitamin E is unknown. Rhabdomyolysis also was accompanied by rapid weight gain of 7% to 15% of the body weight of the foal within the 24 to 48 hours preceding the clinical recognition of rhabdomyolysis and was attributed to fluid accumulation (edema) within the affected musculature. Affected foals may show cardiac and renal dysfunction as well. Foals with severe rhabdomyolysis had a poor prognosis. Because of the severity of this complication in foals presented for sepsis, the recommendation is thatall foals presented for sepsis, prematurity, and failure of passive transfer that have mild elevations in CK activity, low GSHPx activity, or low serum vitamin E concentrations be treated with selenium or vitamin E in addition to the therapies directed at their other underlying problems.

9.14.3 GLYCOGEN BRANCHING ENZYME DEFICIENCY

Glycogen branching enzyme deficiency is a recently described disorder in the horse and has been documented as a heritable disorder in human beings and cats.[303–305] Affected foals have been presented to referral hospitals for sepsis, prematurity, and failure of passive transfer. At presentation, foals often have concurrent sepsis, which necessitates treatment. These foals typically have elevated liver enzymes and persistent problems with hypoglycemia during hospitalization. Increases in serum CK activity may be present. Foals may die acutely during hospitalization or respond well to therapy and be discharged. Shortly after discharge the foal is discovered dead.

Muscle biopsy from affected horses shows a complete lack of normal glycogen staining. Normal glycogen is lacking in skeletal muscle, heart muscle, and liver. The disorder has been diagnosed only in Quarter Horses and is likely a heritable trait, although the genetic defect in the horse has not been identified to date. Quarter Horse neonatal foals presented for sepsis with persistent hypoglycemia, elevated liver enzymes, and elevated CK activity should be considered to have this emerging disorder.

9.14.4 ARTHROGRYPOSIS

Arthrogryposis is a congenital developmental defect characterized by muscle contracture and fixation of various joints in extension and flexion (Figure 9-14). The primary defect in most cases is believed to be in the skeletal or nervous system. Occasionally, the defect may be in the muscles. In such cases the muscles may show degenerative changes or atrophy and an increase in adipose and fibrous tissue. These changes also may occur following neurogenic defects. Difficulty ensues in distinguishing primary neuropathic from primary myopathic forms of the disease and results in patients being referred to as suffering from neuromuscular arthrogryposis. In one case, for example, a foal was born following an uncomplicated delivery with a single hindlimb fixed in a 512
flexed position. This foal showed loss of the lower motor neuron cell bodies in the ventral horn of the spinal cord 513
in segments L3 to S4, as well as lesions in the peripheral nerves and muscles of the affected limb. In human beings, most cases are thought to be neurogenic arising from undefined disturbances of the anterior horn cells. Skeletal malformations and connective tissue disorders are rare causes. The infrequent primary myopathic forms are associated with various muscular dystrophies or myotonia and strong hereditary factors.[306]

Figure 9-14 Arthrogryposis in a foal.

The underlying problem resulting in arthrogryposisin foals is unknown, although genetic and environmental factors such as unfavorable intrauterine conditions, uterine malpositioning, and maternal ingestion of locoweed or hybrid Sudan pasture have been suggested.[37,124,306–309] In the horse, detailed examination of neuromuscular tissues rarely has been performed; most cases are suggested to be skeletal in origin. Therefore the relative importance of primary neuropathic or myopathic conditions is unknown.

The extent of the condition varies with involvement of one to four limbs and may include the axial skeleton. Often more severely affected animals are born dead, and dystocia is common. Milder cases such as foals being born with an apparent inability to straighten one fetlock may occur. Affected muscles appear to have lost sarcomeres from the end of the myofibers, possibly because of prolonged flexion of the joint(s) in late gestation. Constant tension seems to restore these sarcomeres.[37]

The recommended symptomatic treatment of arthrogryposis of any cause includes the use of splints, casts, and physiotherapy, as well as surgery[310]; the latter is successful in human infants and calves.

9.15 Miscellaneous Disorders

9.15.1 ATYPICAL MYOGLOBINURIA

Sudden death from exertional rhabdomyolysis is rareand usually occurs in an animal that has undergone some degree of exertion before the attack. Severe and often fatal attacks of a condition with similarities to exertional rhabdomyolysis have been reported in the United Kingdom in groups of animals out at pasture with no history of sudden exertion.[311] The condition has been referred to as atypical myoglobinuria.

9.15.1.1 Pathophysiology

Factors common to many atypical myoglobinuria cases include adverse climatic conditions before the outbreak and the availability of tree bark, often on dead wood. This atypical syndrome characteristically affects a group of horses over a short period of time, and thereforethe possible predisposing trigger or etiologic factor is thought to be environmental or toxic. No consistent abnormality in selenium or GSHPx values has been seen. One affected horse appeared to have a low liver vitamin E concentration, although another animal affected in the same outbreak had an apparently normal value.[311] In some but not all cases *Trichoderma* spp. fungi were isolated from grass and wood taken from the fields grazed by the affected horses. Mycotoxins therefore have been suggested as being of possible significance.

No access to toxins such as monensin or salinomycin was demonstrated in any case. Oak trees with acorns were not always present, and gastrointestinal signs associated with acorn poisoning were not observed.[70] Spraying with an atrazine herbicide occurred before one outbreak.[312] Simazine residues were not thought to be at toxic levels and clinical signs were not those seen with triazene herbicide toxicity (i.e., severe colic, cessation of eating and drinking, and a dog-sitting posture).[311]

The cause of atypical myoglobinuria therefore hasnot been identified. In horses that died, the precise causeof death was uncertain, but damage to the heart and diaphragm in association with biochemical alterations such as hypocalcemia may have been important. Renal failure may be a contributory cause but is unlikely to be the primary cause of death.

9.15.1.2 Clinical Signs

Atypical myoglobinuria occurs most frequently in horses and ponies grazing pasture of low quality. One or more animals in a group may be affected. A sudden onset of stiffness unrelated to exertion occurs, soon followed by severe myoglobinuria. Temperature, heart rate, and respiration rate are generally within the normal range. No age, sex, or breed predilection has been observed, but few cases have been investigated. Of cases that have been well documented, progression of clinical signs is rapid and mortality is high. Despite profound weakness and recumbency, many affected horses do not appear to be in any distress or pain, and they eat and drink well, even when recumbent. Serum CK activities are greatly increased, and advanced myodegeneration of all muscles, including the heart, may be present.[311]

Myodegeneration indistinguishable from that seen in exertional rhabdomyolysis under the light microscope has been found (although fiber preference was not determined).[306] Large hyperchromatic hepatocyte nuclei were observed in some liver sections together with patchy vacuolation and infiltration of neutrophils into the portal areas. Pink proteinaceous granular material tended to be present in the kidney tubules and within Bowman's capsule.[311] Skeletal abnormalities may not be obvious on gross postmortem examination.

High CK activity (often >5000 IU/dl) caused by myodegeneration is observable. AST activity also tends to be 513
increased greatly. High sorbitol dehydrogenase values (up to 28.8 IU/dl; laboratory reference range, 4 to 15 514
IU/dl) were found in several cases in one investigation.[306] Hypocalcemia may occur, especially in the terminal stages. Myoglobin usually is present in a sufficiently high concentration in the urine to be detectable by electrophoresis on cellulose acetate.

9.15.1.3 Treatment

Because the cause of the condition is unknown, symptomatic treatment is recommended, including intensive fluid therapy, which should be based on biochemical monitoring. One should monitor the calcium status in particular, because horses may become hypocalcemic. Feeding a readily available source of calcium may be of benefit in some cases.

9.15.2 POSTANESTHETIC MYASTHENIA

Postanesthetic myasthenia has been reported in three horses.[313] The condition could be a form of botulism or a drug-induced myasthenia. The characteristic signs were a difficult recovery from anesthesia, lack of any facial expression, flaccid tongue, mydriasis, an inability to raise the head, and dysphagia. All three patients recovered totally with supportive care.

9.15.3 POLYMYOPATHY

An aged pony mare developed a slowly progressive stiffness of gait that varied in severity. She was reluctant to move or eat and exhibited general loss of muscle bulk. The condition responded temporarily to NSAIDs. Needle EMG revealed a diffuse polymyopathy. Muscle histopathologic study revealed shrinkage, fragmentation, loss of muscle fibers, replacement of muscle bundles with adipose tissue, and some evidence of myofiber regeneration. The cause of the condition was unknown. Other cases of polymyopathy of unknown cause have been suspected in horses and await documentation and further categorization.

9.15.4 SUPPURATIVE MYOSITIS: ABSCESSATION

Suppurative myositis may be hematogenous in origin or result from penetrating wounds, intramuscular injections, or an extension of an infective focus in an adjacent or distant structure. *Streptococcus equi* is a frequent cause, because injections of a variety of intramuscular vaccinations lead to abscessation. Affected horses often initially have an ill-defined cellulitis, which may heal, progressto a classic organized abscess, or in the case of certain staphylococci, may extend, resulting in extensive muscle damage. Abscesses may heal slowly, expand, or fistulate to the surface. Once fistulated, abscesses may collapse and heal, usually with scar tissue, or persist as chronic granulomata (especially *Staphylococcus aureus* in the neck and pectoral region).[37] *Corynebacterium pseudotuberculosis* also may be isolated from large abscesses in various muscles, in particular, the pectorals.

A significant geographical variation appears in the clinical signs with *C. pseudotuberculosis* infection. Worldwide, ulcerative lymphangitis—usually with sores, abscesses, fever, lameness, anorexia, and lethargy, which may progress to chronic lameness and weight loss—is the most common condition. In the western United States, especially in the more arid parts, the organism tends to be associated with ventral midline, inguinal, and pectoral abscesses, although internal abscesses may occur. The condition has been referred to as pigeon fever (after the swollen pectorals giving the appearance of a pigeon breast), or alternatively as dryland distemper or Colorado strangles (after its geographical distribution).

Suppurative myositis can occur at any time of the year but is more common in late summer, fall, and early winter. One or more horses within a group may be affected. Outbreaks in a number of horses at a single establishment have been reported. The organism can survive in the soil and enters the body via lesions in the skin or mucous membranes and spreads via the lymphatics. Insect vectors may be involved. Clinical signs varywith the stage of the condition and the site of the abscess(es).[298,314] The affected horse may be pyrexic and anorectic during the maturation phase of the abscess. Ventral pitting edema, lameness, weight loss, and depression also may occur. If the abscesses are located in the axillary or inguinal regions, the affected animal can be very lame and is more likely to be intermittently febrile. Such cases can be difficult to diagnose because the abscesses may take weeks or even months to develop fully. Increased white blood cell counts and plasma fibrinogen concentration may be observed, although in the more chronic stages few clinicopathologic changes are seen. *C. pseudotuberculosis* infections are less likely than staphylococcal or streptococcal abscesses to result in an increased white blood cell count or plasma fibrinogen concentration. Abscesses typically form deep in muscles and can be large with thick capsular walls filled with a nonodorous, light tan pus. The differential diagnosis includes seromata, tumors, and other bacterial abscesses. One can confirm the diagnosis by ultrasound or culture of any aspirated fluid. Abscesses in the axillary region, in particular, can be difficult to locate, even with ultrasound. A synergistic hemolysis inhibition test detects antibodies to the organism, but the intensity of the antibody response depends on a number of factors, including thickness of the capsule surrounding the abscess and chronicity of the infection. For example, horses with chronic thick-walled abscesses that have been lanced recently may have low or undetectable circulating antibody concentrations, perhaps because antibodies have been used in combating the massive toxin release. The test can be helpful in determining whether one should 514
include internal *C. pseudotuberculosis* abscessation in the differential diagnosis, however. 515

Recommended treatments include encouraging the maturation process via hot poultices, lancing, flushing, and draining. In some cases surgical intervention may be required to expose the abscess adequately. Some controversy exists over the use of antibiotics, especially respecting the timing of administration, which may depend on the stage of abscessation. Antibiotics commonly recommended include procaine penicillin G at 20,000 IU/kg intramuscularly every 12 hours or potassium penicillin G at 40,000 IU/kg intravenously every 6

hours, sulfadiazine-trimethoprim, and erythromycin. Rifampin at 2.5 to5.0 mg/kg orally every 12 hours often is recommended in combination with penicillin. Antibiotic therapy ideally should continue for several weeks.

Prognosis is guarded; some abscesses do not resolve completely with treatment. Some recur when antibiotic therapy is discontinued; others may recur months later. In a few horses, internal abscesses may develop, resulting in chronic weight loss and sometimes ventral edema, ascites, dyspnea, recurrent colic, exercise intolerance, recurrent pyrexia, etc. Abortion also can be a sequela.[298] Avoiding contamination of paddocks via a draining lesion and dealing with contaminated bedding appropriately has been recommended. Good fly control also can be beneficial.

9.15.5 MUSCLE TUMORS

Primary tumors of skeletal muscle are rare, malignant tumors being twice as frequent as benign ones. Rhabdomyosarcomata of the limbs, head, or neck appear as hard, spherical masses deep in the muscle. A significant proportion appears to occur in sites of earlier muscle fiber destruction and repair. Frequently, animals less than 2 years old are affected. Other benign and malignant primary tumors, including lipomata, liposarcomata, fibromata, fibrosarcomata, myxomata, and hemangiosarcomata, can occur in muscles. Metastatic spread to the muscles, especially of malignant melanomas, angiosarcomata, and tumors of the lymphoreticular system, also may occur.[37]

9.16 ACKNOWLEDGEMENT

The author offers great thanks to Susan Pinkus for her help in preparing this manuscript.

9.17 9.1—Pathophysiology and Treatment of Acute Laminitis

Ashley M. Stokes

Susan C. Eades

Rustin M. Moore

Acute laminitis (founder) is a severely debilitating, excruciatingly painful, and potentially career-ending and life-threatening disease of the soft tissues (sensitive and insensitive laminae) of the equine digit. Laminitis is important to all horse owners and trainers and horse enthusiasts because it can occur in adult horses and ponies of any breed or use (athletes or companions/pets). Laminitis usually occurs following other diseases such as acute gastrointestinal tract disease (colic), particularly strangulating obstruction and inflammatory bowel disease (anterior enteritis and enterocolitis); grain overload; retained fetal membranes and subsequent metritis; pleuropneumonia; and other diseases accompanied by endotoxemia. Gastrointestinal tract disease was the most common primary disease in 54% of horses that developed acute laminitis in a study conducted in seven private practices and at a university veterinary hospital.[1] Additionally, support limb laminitis occurs commonly in the contralateral limb because of overload or excessive weight bearing in horses that have a severe non–weight-bearing lameness (fractures, bone or joint sepsis) in the opposite limb.

Laminitis is frustrating for veterinarians because current knowledge and understanding of the pathophysiology and progression of the disease are incomplete, limiting efforts to prevent and treat this devastating disease successfully. Laminitis causes profound emotional stress and economic loss to horse owners and trainers because of the agonizing pain experienced by the horses. Laminitis often leads to poor body condition and prolonged periods of

recumbency with secondary pressure sores. Many affected horses only rise for short periods of time and demonstrate a characteristic stance of rocking or shifting their weight onto their rear feet, which is accompanied by anxiety, muscle fasiculations, and sweating. Approximately 75% of laminitic horses treated at a university hospital did not return to athletic soundness; most of these horses ultimately were euthanatized because of the severe pain associated with separation of the sensitive and insensitive laminae resulting in rotation or distal displacement of the third phalanx.[2]

Fifteen percent of horses in the United States are estimated to be afflicted with laminitis over the course of their lifetimes, and 75% of these horses develop severeor chronic lameness and debilitation that necessitates euthanasia. The percentage represents a substantial number of horses in the United States and worldwide that suffer from this devastating disease and ultimately are destroyed. From an economic perspective the diagnosis and treatment of laminitis is estimated to cost$8 million annually, and the monetary loss of animals euthanized each year following complications of laminitis is approximately $5 million.

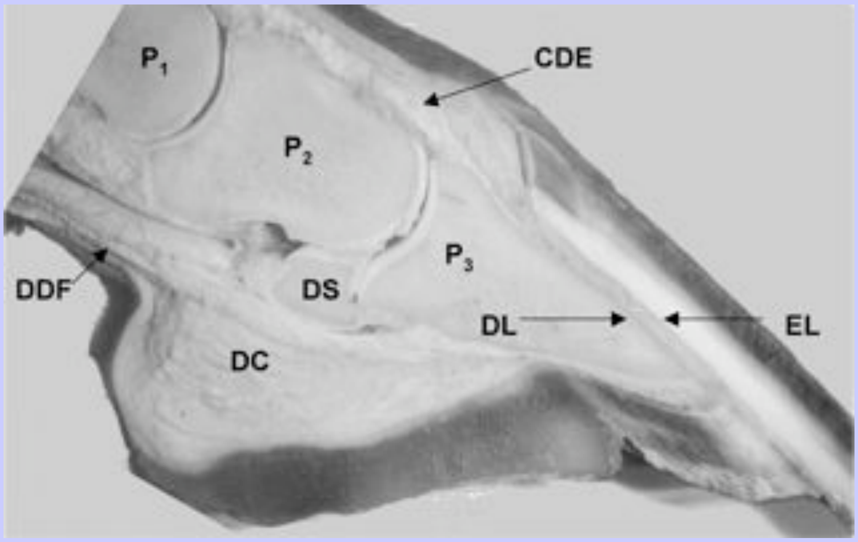
Scientific investigations have shed light on the pathophysiologic events involved with laminitis; however, additional studies are needed to unravel the remaining mysteries regarding the initiation and propagation of laminitis. Currently, numerous and varied therapies are used to prevent and treat laminitis; however, clinicians' preferences and impressions regarding the most effective treatments are based on an incomplete understanding of the initiating events in this disease. Because of the gaps in knowledge of the pathophysiology of laminitis, the effectiveness of the currently used treatments is inconsistent at best. Therefore developing a more thorough understanding of the cascade of events involved with the onset and propagation of acute laminitis should help veterinarians develop more rational, effective, and cost-efficient therapies to prevent and treat a disease with profound humane, emotional, and economic effects on horses, horse owners/trainers, and veterinarians. This section provides a comprehensive review of the current knowledge of the pathophysiology of acute laminitis and presents experimental findings that should contribute to a better understanding of this pathogenic cascade and ultimately may help improve the prevention and treatment of laminitis in horses.

9.17.1 ANATOMY AND PHYSIOLOGY OF THE DIGIT

The normal laminar tissue and its vasculature are unique in numerous aspects. The ability of the equine athleteto 522
walk depends on the integrity of the interdigitating primary and secondary laminae, which structurally unite the 523
hoof wall, distal phalanx, and the sole of the foot into a single unit.[3] The bulk of the hoof is composed of the stratum medium, which is composed of avascular, highly keratinized stratified squamous epithelium. This layer blends with the stratum internum, which comprises the primary and secondary epidermal laminae. Approximately 600 primary laminae form longitudinal grooves for interdigitation with the vascular laminae of the laminar dermis (corium). The laminar corium unites with the subcutis and periosteum of the distal phalanx.[4]

The bones of the digit are the proximal, middle, and distal phalanx and the distal sesamoid bone (navicular bone) (Figure 9-15). The primary joint of the digit is the distal interphalangeal joint composed of the middle and distal phalanx and the distal sesamoid bone. The short collateral ligaments join the distal end of the middle phalanx and the proximal edges of the distal phalanx. The collateral sesamoidean ligaments extend from the distal aspect of the proximal phalanx and insert on the edges of the distal sesamoid bone. A branch of this ligament also inserts on the palmar process of the distal phalanx. The distal sesamoid impar ligament arises from the distal aspect of the distal sesamoid bone and extends to the palmar surface of the distal phalanx. A fibrous connection between the palmar surface of the middle phalanx and the deep digital flexor tendon forms a T-ligament. The deep digital flexor tendon inserts on the palmar aspect of the distal phalanx, and the common digital extensor tendon inserts on the extensor process of the distal phalanx.[4,5]

Figure 9-15 Cross section of the equine digit. P_1, Proximal phalanx; P_2, middle phalanx; P_3, distal phalanx; *DS*, distal sesamoid bone; *DC*, digital cushion; *DDF*, deep digital flexor tendon; *CDE*, common digital extensor tendon; *DL*, dermal laminae; and *EL*, epidermal laminae.



The distal interphalangeal joint capsule joins with the common digital extensor tendon, the collateral ligaments of the distal interphalangeal joint, the distal sesamoid impar ligament, and the T-ligament. The joint capsule has two main pouches, the dorsal pouch and the palmar pouch, and the palmar pouch is divided further into proximal and distal pouches. The digital cushion is a large soft tissue structure located between the base of the cartilages, structures located palmar to the collateral ligaments composed of hyaline cartilage that progress to become predominately fibrocartilage. The digital cushion is composed of fibroelastic tissue, adipose tissue, and a small percentage of fibrocartilage. A venous plexus is also located within the digital cushion.[4]

The nutrients to maintain the integrity of the corium come from the laminar arteries branching from the circumflex artery as it curves around the toe. These laminar arteries course in a distal to proximal direction. The laminar veins that course distally into the circumflexvein remove metabolic wastes and drain into the bulbar vein and digital veins. Arteriovenous shunts betweenthe circumflex artery and vein have been demonstrated in acute laminitis.[4] These shunts could alter hoof temperature by providing a path of rapid flow fromthe laminar arteries to the veins, thus bypassing the laminar capillaries; this cooling effect could decrease the metabolic requirements of the laminae. However, this flow pattern robs the laminae of nutrient flow via its capillary bed. 523

524

The digital arteries and veins supplying the hoofhave unique characteristics. The digital veins are highly muscular compared with veins in other tissues and other species.[6] This muscular wall probably is needed to withstand the high vascular pressures exerted in these dependent tissues. The highly muscular wall is likely responsible for the low compliance of the veins.[7] In exercising horses the pressure in the venous circulation may reach 200 mm Hg.[8] The equine digital arteries and veins are highly sensitive to vasoconstrictive substances, most notably norepinephrine and endothelin. Furthermore, the digital veins are most sensitive in vitro to

vasoconstrictive substances.[9] For example, contraction induced by angiotensin, thromboxane, norepinephrine, serotonin, and endothelin is twice as strong in veins as arteries. The culminating effects of low compliance and high sensitivity to vasoconstrictive substances predispose the equine digit to high venous pressures, thereby increasing hydrostatic pressure and thus the likelihood of edema formation.

The microcirculation of the equine foot is adapted poorly to handling edema. In normal tissues, three safety factors counteract edema formation, including capillary permeability, pre- to postcapillary resistance, and lymphatic drainage. An impermeability of the capillary endothelium serves as a barrier to fluid and protein transudation, which results in a higher gradient between the capillary and tissue oncotic pressure, favoring movement of fluid into the capillary lumen. Paradoxically, the equine digital capillary bed is highly permeable to fluid and macromolecules and is more permeable than the vasculature of the dog and rat paw.[7] This permeability results in a higher concentration of interstitial protein, favoring edema formation. A high precapillary (arteriolar) resistance and low postcapillary (venous) resistance reduce the capillary pressure, thereby reducing the hydrostatic pressurefor transcapillary fluid filtration. The precapillary-to-postcapillary resistance ratio in healthy horses is comparable to that in other musculoskeletal beds in other species. However, during the prodromal stages of experimentally induced laminitis (either the black walnut extract [BWE] or the carbohydrate overload [CHO] models), the contribution by the postcapillary portion increases, thus favoring edema formation. Lymphatic drainage provides the third edema safety factor. The small diameter and number of metacarpal lymphatics and the hydrostatic gradient to lymph flow reduce the likelihood that lymphatic circulation effectively can protect the foot against edema when the hydrostatic forces in the capillary favor edema formation.[10]

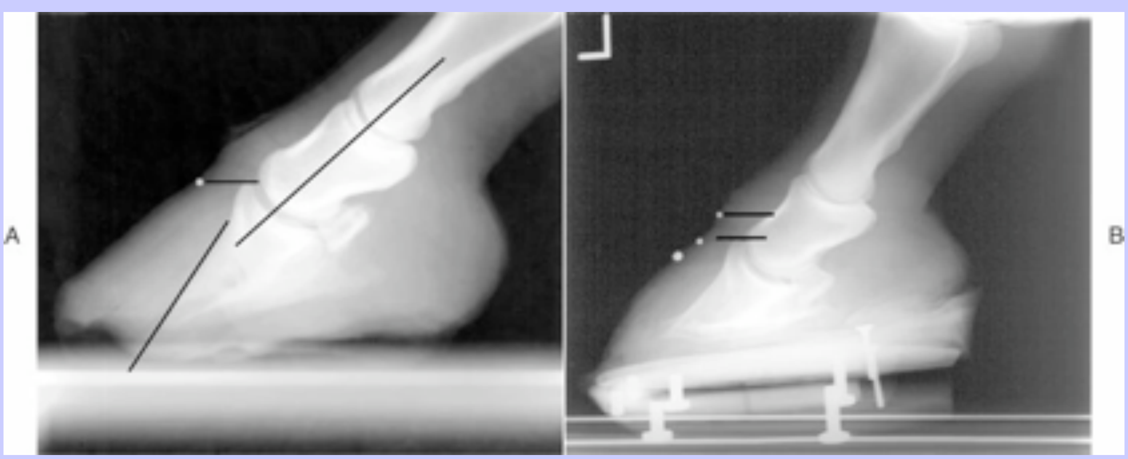
9.17.2 CLINICAL SIGNS AND DIAGNOSIS

Laminitis is a disease that can affect all four feet; however, laminitis most commonly affects the forelimbs because they bear approximately 60% of the mass of the horse.[3] The increased load of the forelimbs compared with the hindlimbs is thought to account for the increased occurrence of laminitis in the forelimbs. To define better the severity of clinical signs exhibited by horses, Obel established a grading system in 1948. Grade 1 is the least severe and states that the horse alternately and incessantly lifts the feet and that lameness is not evident at a walk but is evident at a trot as a short, stilted gait. Horses that walk with a stilted gait but still have a foot lifted are classified as grade 2. Horses with grade 3 laminitis move reluctantly and vigorously resist lifting of a foot. The most severe classification is grade 4, noted by the horse refusing to move unless forced.[11] Other clinical signs characteristic of laminitis are heat present over the dorsal surface of the hoof wall, bounding of the digital pulse (increase in the difference between the systolic and diastolic digital arterial pressure), sensitivity to hoof testers, swelling of the coronary band, and alteration of stance to redistribute weight to the hindlimbs (sawhorse stance or rocking of weight to the hindlimbs) if laminitis is principally affecting the front limbs (Figure 9-16). More severe signs are a dropped sole or palpation of a depression located at the level of the coronary band, both indications of rotation or distal displacement (sinking) of the distal phalanx within the hoof wall.[5,12] Lateral radiographs of the digit are indicated for detection of rotation and distal displacement of the distal phalanx within the hoof capsule (Figures 9-17, *A* and *B*). The placement of a radiopaque marker 1 cm below the coronary band is helpful when determining the presence of distal displacement of the distal phalanx. The presence of a linear radiopaque marker in the block on which the horse stands is helpful to assess the angle and degree of rotation.

Figure 9-16 A few of the clinical signs commonly associated with laminitis include weight redistribution, pressure sores, and poor body condition as demonstrated in this horse with forelimb laminitis.

524

Figure 9-17 A & B **A**, Lateral radiograph of the equine digit demonstrating rotation of the distal phalanx within the hoof capsule. Note the black line drawn parallel to the dorsal surface of the phalanx and the angle this forms with the radiopaque marker in the block, which is used to aid in the assessment of the magnitude of rotation. The line drawn axially through the proximal and distal interphalanageal joints should be approximately parallel to the dorsal surface of the distal phalanx in the normal horse, and deviation from this angle represents distal phalanx rotation. Also, note the placement of the round radiopaque marker in the dorsal hoof wall 1-cm distal to the coronary band, which is used to evaluate distal displacement of the phalanx. This marker should be approximately at the level of the extensor process in normal horses. The vertical distance between this line and the line drawn at the level of the extensor process represents the degree of displacement. **B**, Lateral radiograph of the digit demonstrating marked distal displacement of the phalanx. Note the three radiopaque markers that were used for serial radiographic evaluation. These can also be helpful in assessing dorsal hoof wall growth. (Courtesy Dr. Ralph E. Beadle.)



9.17.3
HISTOPATHOLOGIC FINDINGS

Histologic study of laminar changes during laminitis has been performed 48 to 96 hours after induction of laminitis with cornstarch or wheat flour gruel. Lameness begins approximately 30 hours after administration of the induction ration.[10] Evaluation of a progression of lesions by these studies is difficult because the onset and severity of lameness varies substantially from horse to horse. Studies using these models are confounded further by the fact that approximately 10% of horses appear to be resistant to the ration.

Following the onset of lameness, the initial histologic alteration occurs in the digital vasculature, including swelling of the endothelial cells and mild edema formation.[13] Laminar capillaries become obstructed with erythrocytes within 8 hours. Within 6 to 12 hours, a perivascular leukocyte infiltration occurs that then dissipates as the inflammatory cells migrate into the epidermal layer. Arteriolar endothelial cells become deformed because of cytoplasmic processes that extend into the lumen. Microvascular thrombi and accompanying severe edema formation occur within 24 hours, and hemorrhage occurs within the primary dermal laminae by 72 hours.

Primary histologic alterations of the laminae occur within 8 hours after lameness develops.[13] Initially, thinning and lengthening of the lamellar structures is accompanied by reduction, flattening, and displacement of epithelial cells. The secondary laminae become redirected such that laminae nearer the base of the dermal lamina are directed toward the coffin bone and those nearer the laminar tips are directed toward the hoof wall. Morphologic alterations following epithelial cell damage include swelling, vacuolization, nuclear swelling and pyknosis, and leukocytic infiltration of the secondary epidermal lamina, which is observable as early as 24 hours after the onset of lameness.

9.17.4
PATHOGENESIS

Development of acute laminitis often follows other primary diseases; therefore the mechanisms involved in the pathogenesis of laminitis are most likely numerousand interrelated. Currently, three main theories have been 525
526 proposed regarding the pathogenesis of acute laminitis in horses: the ischemic/vascular, mechanical/traumatic, and metabolic/enzymatic theories. However, almost certainly multiple factors from each theory are part of the pathogenesis of the disease.

The ischemic/vascular theory poses altered digital perfusion as the initiating factor in the cascade of events that leads to metabolic dysfunction and structural failure of the laminae.[13] Although the pathogenesis of laminitis is not understood fully, the initial vascular mechanisms are characterized by hypoperfusion caused by venoconstriction; laminar edema formation; opening of arteriovenous shunts, allowing blood to bypass laminar tissues and leading to tissue ischemia; necrosis of the interdigitating laminae; and ultimately mechanical failure with rotation or sinking of the distal phalanx away fromthe hoof wall.[10,14–16] Venoconstriction is considered the initiating factor causing decreased laminar perfusion.[17] Increased venoconstriction results in increased vascular resistance and capillary hydrostatic pressure. Increased capillary hydrostatic pressure forces fluid out of the capillaries and into the interstitium, thereby increasing laminar interstitial pressure. When tissue pressure exceeds the capillary critical closing pressure, the capillaries collapse, leading to tissue ischemia. Increased pressure in a confined anatomic space can affect blood flow of those tissuesand can lead to ischemia of those tissues; this condition is referred to as compartment syndrome. Allen, Clark, Moore, et al. hypothesized that horses develop compartment syndrome within the digit during the developmental stages of laminitis, leading to laminar ischemia.[10] Formation of arteriovenous shunts at the level of the coronary band is hypothesized to

reduce blood flow futher.[17,18] The digital laminae undergo necrosis after prolonged ischemia. Separation of the interdigitating sensitive and insensitive laminae develops, and distal phalanx rotation, distal displacement, or both subsequently occur.[19]

Garner, Coffman, Hahn, et al. introduced the hypothesis that the predominant cause of laminitis after CHO overload was a disturbance in digital blood flow, which occurred during the onset of the syndrome after CHO overload of the gastrointestinal tract.[15] Using contrast radiography, researchers demonstrated reduced perfusion in the terminal vasculature of the foot.[20] Garner, Coffman, Hahn, et al. also determined that the changes in digital perfusion are associated with significant systemic hemodynamic changes, including a decline in right atrial pressure, diastolic systemic arterial pressure, and systolic systemic arterial pressure, which reaches a maximum about 16 hours after administration of starch via nasogastric tube.[21] This pressure drop is followed by a steady increase in right atrial pressure, diastolic arterial pressure, and systolic arterial pressure. These results suggest that appreciable cardiovascular changes occur in horses with laminitis, and increased release or activation of vasoactive mediators occurs.

The mechanisms responsible for digital hypoperfusion were evaluated first by tracing radioactive albumin particles through the foot during the development of laminitis. A reduction in laminar capillary perfusion and shunting of blood at the level of the coronary band suggests the presence of arteriovenous anastomoses (arteriovenous shunts) that open during the development of laminitis, resulting in hypoperfusion of the digital microcirculation.[14] Although Allen, Clark, Moore, et al. demonstrated a reduction in digital blood flow and perfusion at 16 hours after experimentally induced CHO overload,[10] Pollitt and Davies recently demonstrated increases in hoof temperature, suggesting an increase in blood flow to the tissues encased within the hoof capsule.[22] Conversely, Hood, Wagner, Brumbaugh, et al. demonstrated a decrease in hoof temperature after CHO overload.[23] Hinckley, Fearn, Howard, et al. recently used infrared techniques to demonstrate stasis of blood within the hoof during early laminitis.[24] Studies suggest that arteriovenous shunts open between the laminar arteries and veins,[25] diverting blood flow from the capillaries providing nutrients to laminar tissues while increasing hoof wall temperature. Collectively, these studies suggest an increase in resistance in the digital circulation (possibly in the venous circulation, causing stasis) diverting blood to low resistance shunts. These results illustrate the difficulty of evaluating capillary perfusion by use of temperature data alone.

In subsequent studies using the isolated perfused digit, the specific hemodynamic forces acting on the laminar microcirculation in healthy and experimentally induced laminitic horses have been defined extensively.[10,16,26] Several alterations in the digital vascular system of horses with experimentally induced Obel grade I laminitis (CHO overload and BWE models) have been identified.[10] Of particular importance is the finding that the precapillary-to-postcapillary resistance ratio is decreased in the prodromal stages of laminitis. This imbalance increases the hydrostatic force in the capillary, promoting the fluxof fluid across the capillary bed within the foot and resulting in laminar edema while capillary permeability remains normal. These findings support the hypothesis that increased venomotor tone initiates laminitis.

Although laminitis induced by CHO overload or BWE are accompanied by increases in capillary pressure and tissue pressure, differences between the two models have been observed.[10,26] The severity of the venoconstriction accompanying laminitis induced with BWE was less than that associated with CHO overload. These less severe changes with BWE may be caused by a difference in the pathophysiology of the disease or may be because the Starling's forces accompanying laminitis caused by BWE were evaluated at a different stage 526
of the disease. Adair, Gole, Schmidhammer, et al. recently determined that laminar microvascular blood flow 527

decreases in the first 1 to 2 hours after administration of BWE.[27] This initial decrease then is followed by a return of laminar microvascular blood flow to near baseline values. Then at about 8 hours into the disease, laminar blood flow again decreases corresponding to the development of clinical signs of laminitis. The time course of blood flow changes associated with CHO-induced laminitis has not been studied for comparison. More information is needed to determine the relationship between CHO overload andBWE-induced laminitis.

Weiss, Evanson, McClenahan, et al. demonstrated a significant increase in platelet-neutrophil aggregates, but not platelet aggregates or clotting times, in ponies administered CHO overload.[28] Furthermore, pretreatment with a platelet aggregation inhibitor prevented laminitis in ponies administered CHO overload, highlightingthe importance of these activated cell aggregates in the pathogenesis of laminitis.[29] Local production of platelet-activating factor within the enterohepatic circulation may result in formation of platelet-platelet and platelet-neutrophil aggregates that lodge in the microvasculature of the digit.

The ischemic hypothesis has focused on digital hemodynamic alterations; however, the initiating mediator or mediators that trigger these vascular alterations have yet to be determined. Katwa, Johnson, Ganjam, et al. recently demonstrated that the concentration of endothelin-1, a potent endothelial-derived vasoconstrictor, in laminar connective tissues obtained from experimentally induced acutely laminitic horses and naturally occurring chronically laminitic horses was increased compared with a control group.[30] Another study examining the potent vasoconstrictor endothelin-1 found that in vitro, contractile responses of equine palmar digital veins were more than 3 times greater than responses of arteries to endothelin-1 administration.[9,31–33] Previous research has demonstrated that nitric oxide donor administration improves digital perfusion and reduces the bounding digital pulses associated with acute laminitis in ponies.[34,35] Nitric oxide is an endothelial-derived vasodilator that plays a role in regulating endothelin-1 release.[36] Based on these studies, an imbalance in endogenous endothelial-derived substances, such as endothelin-1 and nitric oxide, possibly may play a role in the vascular alterations that occur during the development of laminitis in horses.

The mechanical or traumatic theory is based on causes of laminitis resulting from direct trauma to the digit and not a primary systemic disease leading to the development of laminitis.[12] Common examples of traumatically linked laminitis are road founder, laminitis following unilateral lameness of the opposite foot (support limb laminitis), and development of laminitis after long trailer rides.[12,37] The exact mechanisms that lead to structural failure of the laminae are unknown, but several hypotheses have been suggested. Excessive force applied to the dermal and epidermal laminar interdigitations may initiate an inflammatory response with vasospasm, thereby increasing capillary hydrostatic pressure, leading to edema formation and ultimately resulting in a compartment-like syndrome much like that of the ischemic/vascular theory. Another hypothesis is that application of excessive force results in tearing of the dermal and epidermal laminar interdigitations; the inflammatory response or vasospasm or both then ensue, leading to ischemic damage of the laminar interdigitations.[12]

The toxic or enzymatic theory states that the fundamental event leading to the failure of the laminar interdigitations is delivery of blood-borne toxins to the epidermal laminae resulting in weakening and loss of cellular attachments.[38] Based on this theory, the loss of these cellular attachments precedes the vascular and inflammatory alterations described within the ischemic theory. Pollitt and Davies state that instead of the hypoperfusion demonstrated by ischemic theory proponents, hyperperfusion of the digit is responsible for delivery of these toxins to the laminar tissues.[22] Pollitt and Daradka state that the targets of the blood-borne toxins are the mediators of enzymatic remodeling that are a part of the normal processes involved in the movement of the continually proliferating hoof wall past the distal phalanx. Laminin and type IV and type VII collagen are components of the laminar basement membrane. The enzymes metalloproteinase-2 and

metalloproteinase-9 are believed to dissolve these substances, and under normal physiologic states, controlled dissolution allows the movement of epidermal laminae past the dermal laminae as growth occurs.[38,39] Excessive activation of these enzymes leadsto uncontrolled dissolution of the basement membrane components, resulting in separation of the epidermal laminae from the dermal laminae. Laminar samples from horses 48 hours after induction of laminitis using the CHO model demonstrated loss of basement membrane attachments.[40] In horses with naturally acquired acute and chronic laminitis, zymography of laminar connective tissues found increased activation of extracellular metalloproteinases compared with nonlaminitic horses.[41] Activation of the metalloproteinases is hypothesized to be induced by the exotoxin(s) from *Streptococcus* species, especially *Streptococcus bovis*, a gram-positive bacteria found in the normal cecal flora.[38,42,43] Using the CHO model, researchers have identified changes in the bacterial population of the cecum with fermentation of the CHO, resulting in excessive lactate production, rapid decline in intracecal pH, and death of cecal bacteria including *Streptococcus* species.[43,44] Based on this theory and its supporting data, prevention of laminitis should aim 527 toward abolishing activation of the enzymes responsible for the dissolution of the basement membrane. 528

Obviously, numerous mediators are present in acutely laminitic horses; therefore the authors believe that a single unifying mechanism is unlikely to cause the laminar damage. Most likely, vascular derangement and direct mediator damage coincide.

9.17.5 CURRENT TREATMENT

Treatment of laminitis remains empiric and often based on the experience and preference of the clinician. Effective treatment of laminitis requires aggressive and appropriate treatment of the primary disease process. Additionally, the cornerstones of treatment of horses with acute laminitis are directed at different components of the pathophysiologic process. One should consider acute laminitis a medical emergency and should institute treatment immediately after clinical signs develop or, preferably, before the onset of clinical signs. Effective prevention and treatment of acute laminitis involves a multitherapeutic approach. The authors believe the goals of treatment are to eliminate or minimize any predisposing factors; reduce the pain/hypertension cycle; reduce or prevent the magnitude of permanent laminar damage; improve or reverse deleterious digital or laminar hemodynamics, including normalizing digital Starling's forces; and prevent further movement of the distal phalanx within the hoof capsule. Considerable controversy exists regarding the treatment of laminitis because of the lack of understanding of the pathophysiology of this disease. The authors developeda therapeutic plan by concentrating on the cornerstones of treatment of acute laminitis, which include treating the primary disease, giving analgesic and antiinflammatory therapy, restoring normal digital Starling's forces, normalizing digital blood flow and hemodynamics, providing mechanical support to the third phalanx via frog support, and limiting mechanical forces on the interdigitating attachments of the dermal and epidermal laminae.

To institute preventive treatment for laminitis, one must identify those horses at risk. Many of the primary diseases thought to predispose horses to develop laminitis are associated with circulating endotoxin. One of the most important preventive measures is combating the effects of endotoxemia and sepsis effectively by decreasing the severity of the primary illness. Recommended treatments include administration of mineral oil (if the horse engorged on grain), intravenous fluids, parenteral antibiotics, nonsteroidal antiinflammatory drugs, and hyperimmune serum or plasma. Other preventive treatments include heparin, aspirin, vasodilators, corrective hoof trimming and shoeing, placement of the horse in a deeply bedded stall, and frog support. Many of these preventive measures also are instituted therapeutically.

The authors believe one of the most important considerations in developing a preventive and therapeutic plan is to attempt to normalize digital Starling's forces. Because of the anatomy of the normal lamina and hoof and the

microvascular alterations that develop with the onset of laminitis, horses are predisposed to developing significant laminar edema, which leads to compressionof the nutrient capillaries, resulting in laminar ischemia, reduction of metabolic waste removal and ultimately laminar necrosis and degeneration. Therefore one should take steps to normalize these Starling's forces. The best approach is to make sure plasma oncotic pressure is sufficient by supplementation with plasma or another colloidal solution such as hydroxyethyl starch or plasma. Additionally, one should take care when administering intravenous fluid therapy to horses with acute laminitis or those predisposed to develop it, because excessive intravascular volume caused by overzealous fluid administration could tend to perpetuate development of laminar edema in horses with abnormal digital hemodynamics (i.e., increased capillary hydrostatic pressure). Therefore the authors suggest that one monitor fluid therapy carefully so as not to administer fluids in excess of the volume needed to maintain normal hydration.

Because many clinicians believe, and substantial scientific data suggest, that the initiating event in laminitis is a vasoconstrictive event, treatments directed at improving digital blood flow and laminar perfusion often are suggested. The authors believe that an ischemic episode caused predominantly by venoconstriction is the initiating event and recommend administration of drugs to cause vasodilation and subsequently improve digital blood flow, Starling's forces, and laminar perfusion. The drugs most commonly used to improve digital blood flow are acepromazine (0.03 to 0.06 mg/kg intramuscularly every6 to 8 hours for a minimum of 3 days), isoxsuprine hydrochloride (1.2 mg/kg orally every 12 hours), and topically applied glyceryl trinitrate (2 to 4 mg/hr). These drugs have been shown not to alter blood flow or laminar perfusion in normal, nonlaminitic horses; however, their effectiveness in laminitic horses has not been reported.

With the recent suggestion that vasoconstriction early in the onset of laminitis may have a protective effect by limiting the delivery of gut-derived toxic substances that have direct cellular damaging effects to the laminae, some investigators and clinicians suggest that vasodilation may not be the most appropriate vascular effect in the developmental stages. Based on this information, some investigators and clinicians suggest preventing the vasodilatory events during the developmental phases of laminitis to reduce delivery of these substances to the laminae. Additionally, exercise of an intensity that increases core hoof temperature or local anesthesia of the 528
palmar or plantar nerves results in hoof wall warming and, by inference, vasodilation; therefore intense exercise 529
is believed to be contraindicated during the early phases of laminitis. One method reported to be effective in preventing the vasodilatory phase that has been recommended is to soak the feet in crushed ice or cold water. This is a time-honored treatment; however, one would need to bathe the hooves continuously and during the developmental phase before the onset of lamellar damage. Otherwise, vasodilation and a rebound hyperemia would occur once the feet were removed from the cold therapy. The ability to keep the feet cold enough to alter blood flow is difficult practically speaking, and the normal regulation of blood flow (based on tissue needs) may overcome cold-induced vasoconstriction. As many times is the case, the developmental phase (preclinical signs) goes unnoticed and lamellar damage has occurred by the time treatment is initiated. At this stage, blocking delivery of cytotoxic substances would be too late, and the authors think that reestablishment of flow is important for oxygen and nutrient supply to the tissues and to remove potential cytotoxic substances and cellular wastes. Although the understanding of the pathophysiology of laminitis is incomplete, based on the current, collective scientific literature, the authors do not believe that reducing digital blood flow is justified and actually may cause exacerbation of the disease, depending on when in the courseof the disease the cold-induced digital vasoconstriction occurs.

Antiinflammatory medications are indicated to decrease inflammation, edema, and pain associated with laminitis. Pain relief helps interrupt the pain-catecholamine–induced vasoconstriction cycle. Phenylbutazone appears to have the best antiinflammatory and analgesic effect of any of the nonsteroidal antiinflammatory drugs commonly used in horses. One can administer a dose of 2.2 to 4.4 mg/kg of phenylbutazone intravenously or

orally every 12 hours. Alternatively, one can administer flunixin meglumineat 0.5 to 1.1 mg/kg intravenously or orally every 8 to12 hours. A dose of 0.25 mg/kg flunixin meglumine administered intravenously every 8 hours interrupts eicosanoid production associated with endotoxemia. One can use phenylbutazone concurrently with flunixin meglumine to control foot pain and endotoxemia if each is given at the lowest dose rate and the horse is hydrated adequately. One can administer ketoprofen at 2.2 mg/kg intravenously every 12 hours. Dimethyl sulfoxide (DMSO) is an antiinflammatory drug that scavenges hydroxyl radicals, decreases edema, and therefore is used to counteract the effects of ischemia-reperfusion injury. Although the involvement of ischemia-reperfusion and oxygen free radicals in the pathogenesis of laminitis is unclear, the fact that a biphasic decrease in laminar perfusion normalizes or increases during the intervening period suggests that hyperemia and subsequent ischemia-reperfusion injury may play a role. The reason DMSO has not been shown to be particularly effective in preventing or treating laminitis could be that ischemia-reperfusion injury does not occur or the dose or timing of DMSO is not appropriate. One should administer DMSO, if used, at a dose of 0.1 to1.0 g/kg intravenously diluted in a polyionic fluid with dextrose to a concentration of 10% to 20% every 8 to12 hours. Some clinicians prefer to place DMSO topically on the coronary bands.

Because microthrombi and platelet-platelet or platelet-neturophil aggregates have been shown to form during laminitis, some clinicians prefer to administer heparin or aspirin to horses as a preventive or therapeutic agent. One can administer heparin using several regimens, but administration often is subcutaneous at a dose of approximately 20,000 to 40,000 units per 450-kg horse. Heparin leads to microagglutination and a subsequent decrease in packed cell volume. No evidence indicates that administration of heparin prevents the onset of laminitis. Aspirin oftenis administered at a dose of 10 to 20 mg/kg orallyonce every 48 hours. Aspirin irreversibly inhibits platelet cyclooxygenase and therefore production of thromboxane, which should decrease platelet aggregation and vasoconstriction.

Efforts to reduce mechanical forces and stabilize the distal phalanx are imperative to effective treatment of acute laminitis. Horses should not be exercised during the acute stages because this can lead to increased mechanical forces that could lead to shearing of laminae. Owners should bed the stall deeply with sand or other material that provides support to the frog and provides some cushion if the horse spends long periods recumbent. Providing early and effective mechanical support of the distal phalanx can spare weakened, separating lamellae and improve the outcome. Ideally, one should institute mechanical support before or at the onset of foot pain. Frog support is one of the more effective methods of providing support to the distal phalanx and can be achieved by using roll gauze taped to the frog in the shape of a triangle. One also can use a commercially available triangular, rubber frog pad. Using a moldable material such as dental putty or a thermoplastic material, one can conform a frog support to the shape and sulci of the frog and sole, allowing for a more effective distribution of the mechanical support to the frog and subsequently the distal phalanx. One must take care to support the frog fully but not allow excessive pressure on the sole because this may increase pain.

Another method to decrease mechanical forces on the distal phalanx is to transect the deep digital flexor tendon to reduce caudal pull on the coffin bone. A deep digital flexor tenotomy has been performed in several horses in
acute and chronic stages of laminitis to prevent or reduce coffin bone rotation. Although short-term outcome was 529
promising, the long-term survival and soundness proved to be less successful. The most appropriate use of a 530
deep digital flexor tenotomy may be to perform it in association with corrective trimming and shoeing during the chronic stages of laminitis to help reverse the amount of rotation.

Each clinician undoubtedly will develop a therapeutic plan based on current literature and on past experiences with the effectiveness of these treatments. The information presented simply represents some of the currently used methods. Obviously, others methods have not been discussed that also may have merit. The effectivenessof preventive and therapeutic measures needs to improve significantly to help manage this devastating disease.

Improvement will become a reality only as researchers collectively work to unravel the remaining mysteries of the pathophysiology of acute laminitis.

9.17.6 PROGNOSIS

Many horses that demonstrate clinical signs of acute laminitis that receive prompt, appropriate medical treatment and mechanical foot support may recover completely. However, some horses, even with mild laminitis, should be withheld from exercise sufficiently until all signs have subsided and only cautiously returned to athletic function. If radiographs demonstrate signs of coffin bone rotation, the prognosis for soundness and even survival must be more guarded. The primary disease that initiates the onset of laminitis also plays an important role in the prognosis and outcome. In general, the greater the degree of coffin bone rotation, the worse the prognosis. Horses with greater than 15 degrees of rotation accompanied by distal displacement into the hoof capsule within 4 to 6 weeks of the onset of laminitis have a poor prognosis. Prolapse of the distal phalanx through the sole often is accompanied by subsolar abscessation. These horses often require extensive, long-term treatment, and the prognosis is grave because of the recurrent, crippling pain and recumbency, and they often require euthanasia for humane reasons. In one study of horses with acute laminitis admitted to a university veterinary hospital, 75% did not return to athletic function and most were destroyed humanely within 1 year because of a lack of response to therapy or development of severe complications.

9.17.7 SUMMARY

Numerous vascular alterations have been identified in acute laminitis. Vascular derangement may lead to impairment of nutrient delivery to laminar tissue, resulting in necrosis. The balance of microvascular pressure in healthy horses favors edema formation. Therefore an imbalance in the forces caused by increased venomotor tone could lead to sufficient increases in tissue pressure to collapse capillaries, open arteriovenous shunts, and lead to ischemic necrosis. Further studies are needed to confirm the relationship of the vascular changes to the damage of the laminar tissue so that appropriate therapies can be developed. Current therapies are varied and inconsistent in their effectiveness and typically result in a guarded prognosis; newer, more effective treatments must be developed as understanding of the pathophysiology of this devastating disease increases.

10 CHAPTER 10 DISORDERS OF THE NEUROLOGIC SYSTEM

Stephen M. Reed

Frank M. Andrews

10.1 10.1—Neurologic Examination

Stephen M. Reed

Assessment of the central nervous system in horses may seem a difficult task; however, with careful examination and by following a craniocaudal approach, assessment is not difficult. A craniocaudal approach is the most logical and efficient. The examination focuses on the neuroanatomic localization of the lesion or lesions and should be completed as part of the physical examination. Subtle neurologic deficits may be hidden by musculoskeletal disease or missed because of lack of knowledge or understanding of these disorders. To accomplish a complete and accurate neurologic examination, the veterinarian must feel comfortable with the format chosen for evaluating the nervous system and must have knowledge of which musculoskeletal disorders commonly are associated with neurologic disease. Problems such as osteochondrosis of the stifle, hock, and shoulder joints often occur concurrently in horses with cervical vertebral stenotic myelopathy. Examples of typical histories in horses presented for neurologic examination are previous medial patellar desmotomy or bilateral bog spavin in early life. Osteochondrosis of the distal tibia or femur and contracted tendons are examples of conditions that may occur simultaneously. Bilateral bog spavin often is associated with osteochondrosis of the distal tibia or other sites in the tibiotarsal joint. Patellar desmotomy to correct upward fixation of the patella may be necessary because of a conformational problem of the stifle joint or because of abnormal joint proprioception or quadriceps weakness following neurologic disease. The foregoing problem is more commonly associated with neurologic disease than many veterinarians realize, and the gait deficits caused by these lamenesses often mimic neurologic disease.

The goals of a neurologic examination are to establish whether a neurologic problem is present and to determine the anatomic localization of the problem. Being able to account for all clinical signs with a single lesion is ideal; however, if this is not possible, one should consider the presence of multifocal disease or multiple diseases. Following anatomic localization, one must decide what additional testing is necessary to determine the underlying cause of the clinical signs. Cervical radiography, cerebrospinal fluid analysis, and electrodiagnostic testing may be useful in locating and determining the cause of the lesions.

The author always begins the examination at the head and proceeds to the tail, although some segments of the neurologic examination are part of the physical examination. The examiner should proceed in a consistent fashion and should record findings in an orderly manner so as to avoid any part of the examination being omitted. Figure 10.1-1 shows a sample format. One may use the craniocaudal approach for all animals, whether ambulatory or recumbent.

The examination procedure is described elsewhere.[1–12] The author follows the format developed by Mayhew,[1] which divides the examination into five categories: the head and mental status, gait and posture, neck and forelimbs, trunk and hindlimbs, and tail and anus. The functional divisions of the nervous system include the sensory, integration, and motor systems. 533

Before starting the examination, the veterinarian should know the age, sex, breed, and use of the horse, although these are not essential. This information is useful because horses of various breeds behave differently. One should ask the owner about any unusual behavior the horse has exhibited and the date of onset of the behavior. Age is helpful because problems such as cervical vertebral stenotic myelopathy and cerebellar abiotrophy begin at a young age, usually less than 1 year. These problems occur more often in certain breeds. For example, cervical vertebral stenotic myelopathy is most common in Thoroughbreds, and cerebellar abiotrophy most often is observed in Arabians.

10.1.1 Examination

The evaluation of the head should include observation of the horse at rest and during motion; palpation, postural reactions, cranial nerve function, and cervicofacial reflexes; and evaluation of sensation. Evaluation of the head includes observation of the behavior and mental status of the horse. One can complete this portion of the examination partially before handling the horse. A close and careful examination is necessary to evaluate the head and neck posture and its coordination and to identify abnormalities of the cranial nerves. Initial consideration includes the environmental awareness of the horse. A normal horse appears bright and alert and responds appropriately to external stimuli. While the horse is being caught, the examiner can look for unusual behaviors such as yawning, abnormal or aimless wandering, seizures, or circling or head tilt and can begin to assess the vision and hearing of the horse. If the horse shows behavior abnormalities, such as head pressing or aggressiveness, one should note these. If the examiner suspects rabies, then the examiner should take precautions to avoid unnecessary and potentially dangerous exposure.

Lesions of the reticular activating system or the cerebral hemispheres could result in severe signs such as coma or obtundation of consciousness. Horses that have a serious systemic illness also may appear depressed or stuporous. One records the level of consciousness as alert, depressed, stuporous, comatose, or semicomatose. An animal that is depressed may react to its environment in an inappropriate or unresponsive fashion. Stuporous horses may appear to be asleep unless stimulated with pain, light, or noise and often demonstrate impaired reactivity.

Head posture and coordination are controlled by the cerebellar and vestibular regions of the brain and brainstem in response to sensory input from receptors in the head, limbs, and body. Examining the head and neck posture with the horse at rest, while eating, and while moving is helpful. Careful examination of the vestibular region is important because many horses develop a head tilt resulting from head trauma, an inner ear infection, or a guttural pouch infection. A head tilt is characterized by the poll deviated about the muzzle and must be distinguished from abnormal or unusual turning of the head as may occur with damage to the forebrain or injury to the cervical vertebrae. Additional signs that may accompany vestibular disease or injury include nystagmus, ipsilateral weakness, and facial nerve paralysis.

Postural abnormalities of the head and neck sometimes can be difficult to distinguish from head tilt. Horses with torticollis of the head and neck may have a congenital abnormality of the vertebrae or may have injured the muscles of the neck region. Careful examination, including palpation, should help identify fractures of the cervical vertebrae or painful muscles caused by trauma or an injection reaction. In some horses, radiographs of the cervical vertebrae may be useful to confirm a fracture or osteomyelitis. Blindness sometimes can lead to an abnormal head or neck posture.

The cerebellum helps regulate rate and range of motion. With damage to this area a horse often shows fine resting tremors of the head that worsen with intentional movements.[3] One may observe this tremorous movement of the head and neck in the newborn or young foal, but it is not normal in older foals and adult horses. In young Arabians and a few other breeds, a condition of cerebellar abiotrophy has been reported.[1–3] Horses with this condition show a hypermetric gait, failure to blink when exposed to bright light, and absence of a menace response.

After evaluating the alertness, mental attitude, head and neck posture, and coordination of the horse, the examiner should examine the cranial nerves closely. Examination from first to twelfth cervical vertebrae helps to ensure that a subtle lesion along the brainstem is less likely to be missed, although in fact the examiner assesses

many of the cranial nerves simultaneously on approach to the horse. The examiner evaluates facial symmetry, facial sensation (including sensation inside the nares), head posture, eyes, nose, mouth, jaw tone, pharynx, and larynx. To determine if an animal can smell is usually not as important, but determining if it can see, hear, breathe, and swallow is critical.

Examination of the eyes should include evaluation of the blink or menace response, the ability of the horse to negotiate in a strange environment, pupillary light response, and in some cases a funduscopic examination. If a horse has a lesion of the eye or optic nerve, the lesion will result in complete or partial ipsilateral blindness. To develop contralateral blindness the horse would have to have a lesion in the optic tract or the lateral geniculate nucleus.[1]

Examination of the face should include evaluation of pupil size and symmetry, which are under control of the autonomic nervous system and are affected by environmental light and level of fear or excitement. To test the 536
pupillary response, one should direct a light in each eye and note the constriction of the pupil. Identifying a 537
consensual response in the horse is often difficult when one works alone. A swinging light test has been described.[1] Moving the light from side to side takes advantage of the ipsilateral light response being stronger than the consensual response. The examiner can perform this procedure alone. These reflexes are in the brainstem and are not affected by lesions in the visual cortex.

One possible cause of asymmetric pupils in a horse is Horner's syndrome. This syndrome includes ptosis of the upper eyelid, miosis of the pupil, and protrusion of the third eyelid (nictitating membrane). In addition, the horse has unilateral facial sweating, increased facial temperature, and hyperemia of the nasal and conjunctival membranes. These signs should alert the examiner to the possibility of a previous perivascular injection, a guttural pouch infection, or damage to the sympathetic nerves in the vagosympathetic trunk, which courses from the cranial thoracic spinal cord through the thoracic inlet and upward to the orbit.[5] Loss of sympathetic innervation to the head results in the triad of clinical signs described, with the most prominent initial sign being increased sweating, which is not what one would expect and the exact cause of which is not well understood.[6,7]

Loss of symmetric positioning of the eyes or the presence of abnormal deviation (i.e., strabismus) occurs when a horse has injured the third (oculomotor), fourth (trochlear), or sixth (abducens) cranial nerve or the connections between the eighth (vestibulocochlear) cranial nerve and these nuclei in the brainstem along the medial longitudinal fasciculus. Deviations of the eyes may occur with head trauma or midbrain lesions or can be normal variations in newborn foals.

The nuclei along the fifth (trigeminal) cranial nerve are among the largest nuclei along the brainstem of the horse. The fifth cranial nerve contains motor and sensory branches that supply innervation to the muscles of mastication and sensation to the skin and mucous membranes of the head. Injury to this nerve leads to dropped jaw and ipsilateral loss of, or decreased sensation to, the side of the face and the inside of the nares.

Damage to the seventh (facial) and eighth cranial nerves is common in horses. Injury to the seventh cranial nerve results in unilateral facial paralysis. This nerve contains branches that supply the ears, eyelids, and nares, and so injury to this nerve may affect all or only part of these structures. The most easily recognized sign is deviation of the nares toward the unaffected side coupled with drooping of the eyelid and ear on the affected side. Because this nerve also innervates the salivary and lacrimal glands, loss of or damage to this nerve may cause dry eye and decreased salivation.

Eighth cranial nerve deficits are easy to recognize, because unilateral injury to this nerve results in a head tilt toward the affected side. The eighth cranial nerve is important to hearing and control of balance. Projections

from this nerve pass to the medulla and cerebellum. A horse that has damage to this nerve often appears disoriented and has a head tilt toward the side of the lesion along with abnormal position of the limbs and body and horizontal nystagmus. If the lesion involves the peripheral portion of the vestibular system, then the fast phase of the nystagmus is directed away from the side of the lesion. If the lesion involves the central portion of the vestibular system, the nystagmus may appear vertical, rotary, or horizontal and may not always appear the same, depending on head position.

Horses that have peripheral damage to the vestibular system usually compensate for the deficits in a short time by use of visual and proprioceptive input. Therefore avoiding the use of a blindfold in cases of suspected vestibular disease is judicious. Using a blindfold hampers the ability of the horse to compensate, and the horse may become dangerous. However, blindfolding a horse with a suspected vestibular disease, but no longer showing an obvious head tilt, may be helpful to localize the lesion.

Within the medial compartment of the guttural pouch along the caudodorsal and lateral walls are the ninth (glossopharyngeal) cranial nerve and a branch of the vagus nerve. When a horse develops a guttural pouch infection, these nerves may be damaged, resulting in loss of innervation to the pharyngeal muscles. The clinical signs include dysphagia on the same side as the damaged nerve. If the infection is severe enough to involve the internal carotid nerve, which contains postganglionic sympathetic fibers to the structures of the head and eye, Horner's syndrome results. As mentioned previously, the signs include ptosis of the upper eyelid, enophthalmos resulting in prolapse of the third eyelid, miosis of the pupil, and sweating along the side of the face.

Other diseases one should consider when Horner's syndrome is evident during a neurologic examination include injury or infarction to the cranial thoracic spinal cord, avulsion of the brachial plexus, a hematoma, or tumor invading the sympathetic trunk in the region of the caudal, cervical, or cranial thoracic sympathetic trunk. Mycosis of the guttural pouch can cause damage to the internal carotid nerve or the cranial cervical ganglion along the caudodorsal wall of the guttural pouch. Finally, an injury to or neoplasia of the structures within or just behind the orbit also may cause Horner's syndrome.

Focal sweating in a horse indicates involvement of the peripheral pre- or postganglionic sympathetic neurons. Identification of this problem also can aid in the anatomic localization of a neurologic lesion.[1]

Intact innervation to the larynx and pharynx is important, especially if the horse is to be used as an athlete. The 537
easiest means to evaluate this region is by endoscopic examination of the pharyngeal and laryngeal regions. One 538
can perform throat latch palpation and a laryngeal adductory slap test. Endoscopic examination is helpful and important to a complete evaluation. The innervation of the pharynx and larynx is via the ninth, tenth (vagus), and eleventh (accessory) cranial nerves and the connections of these nerves in the caudal medulla oblongata.

Following careful examination of the mental status and behavior of the horse and of the head, neck, and cranial nerves, the examiner should look for asymmetry of the muscles of the trunk, pelvic region, tail, and anus. Identification of focal sweating, focal muscle atrophy, or increased or decreased pain responses is helpful in localizing signs. In addition, the horse has two cervical reflexes. The cervicofacial reflexes result in a local twitch and drawing back of the lips (smile reflex) when one pricks the skin along the side of the neck down to the region of the second cervical vertebra. Below the region of the second cervical vertebra one should observe a local response.[13]

To evaluate the tail and anus, one should begin by observing the tail carriage at rest and with the horse in motion. The normal tail carriage is straight down but with free movement in all directions. Some normal horses allow the tail to be lifted, giving little resistance, whereas other horses strongly resist and clamp the tail. The usual

response to anal stimulation is to clamp the tail and squat down, although with prolonged stimulation the horse may relax and eventually raise its tail.

10.1.1.1 EVALUATION OF GAIT

Evaluation of the gait of the horse should include examination of postural reactions and may include evaluation of spinal reflexes in young or small horses. Although they may appear weak and ataxic, foals are ambulatory within hours after birth, making it possible to evaluate gait. Because postural reactions are sometimes difficult to interpret in horses, using gait abnormalities to help localize a lesion is essential. The author nearly always places the feet and limbs in an unusual position to observe the response of the horse. Gait abnormalities that are observed commonly in horses with neurologic disease include ataxia, spasticity, and weakness or paresis.[1–3,4,15]

Evaluation of gait is critical because subtle neurologic gait deficits often go unrecognized or sometimes, incorrectly, may be considered insignificant. One should conduct the examination so as to observe the horse at a walk and trot in a straight line and while turning. In some horses, observing the horse negotiate over small obstacles such as a curb is helpful. When possible, the examiner should observe the horse turned free and walking up and down an incline. Elevation of the head and walking on a slope may exaggerate a subtle deficit and make it more noticeable.

One should conduct the examination with the animal at rest to observe its posture, while walking, while trotting, and sometimes while the horse is being ridden. The examiner should pay attention to which limbs show abnormal posture or abnormal movements and must be able to determine whether the horse has a painful, mechanical musculoskeletal problem or a neurologic gait deficit. The examiner must identify the presence of weakness, ataxia, and spasticity in each limb.

The important centers for posture and coordination in the brainstem and spinal cord have been described briefly. These centers are located in the regions of the sixth cervical to second thoracic (T2) and fourth lumbar to second sacral (S2) vertebrae in the spinal cord, along with coordination centers in the brainstem. Horses that demonstrate a wide base stance at rest often have a lesion of the cerebellum or vestibular system or may have conscious proprioceptive abnormalities.

To evaluate the gait of an animal, one begins by observing the horse at a walk and trot. At a walk the examiner can walk alongside, in step with first the rearlimbs and then the forelimbs. This allows the examiner more easily to determine the stride length and foot placement. A weak limb often has a low arc and longer stride length.

One also should observe the horse walking in a circle, on a slope, and with its head elevated. These procedures help to demonstrate if the horse is showing persistent irregular movements with its limbs. Horses with a musculoskeletal problem have been described as being regularly irregular, whereas a horse with neurologic gait deficits shows fewer consistent mistakes when positioning its limbs. Although observing the horse running free in a paddock or round pen and while being ridden is helpful, this is not always possible. The veterinarian must consider certain legal ramifications before asking a person to ride a horse during the examination.

Additional tests that may be helpful during a neurologic examination include blindfolding the horse, walking it over a curb or other obstacle, and walking it with its head and neck extended. One can evaluate the strength and ability of the horse to correct body positions by performing a sway test by applying lateral pressure at the

shoulder, hip, and tail while the horse is standing and walking. One should apply pressure several times while the horse is walking to catch the limb in various stages of weight-bearing. Observing a horse while it is backing is important. When a normal horse is backing, it should lift each leg and place it in a coordinated and appropriate location. Horses with neurologic abnormalities often place the limbs in wide-based positions or lean back and are reluctant or refuse to move. The horse also may step on the rear feet with the front feet.

One should observe the horse closely while being turned in a tight circle. One may identify abnormal wide 538
outward excursions of the rearlimb (circumduction) during this procedure. Additional tests to assess 539
proprioceptive function include a standing sway test in which one applies pressure to the the shoulder. The horse initially should press into the examiner and then lean away, and finally it should step away with the offside limb. The author also crosses the limbs over the opposite fore- or rearlimb to determine if the horse recognizes and tolerates these unusual limb positions. Following this, the author lifts one front limb and force the horse to hop on the opposite front limb in a modified postural reaction.

The examiner should observe the movements of each limb carefully to determine if a deficit is present and should assign a grade to the deficit. The author uses a system modified from the grades described by deLahunta[3] and Mayhew.[1] The severity is graded between 0 and 5. Grade 0 means no gait deficits. A grade 1 deficit requires careful observation to be certain the gait abnormality is caused by a neurologic dysfunction. Grade 2 deficits are moderate but obvious to most observers as soon as the horse begins to move but are still mild to moderate in severity. Grade 3 deficits are obvious and are exaggerated during the negotiation of a slope or with head elevation. Grade 4 gait deficits may cause a horse to fall or nearly fall. When attempting to walk, an animal with these severe deficits often displays abnormal positioning while standing in its stall. Grade 5 horses are recumbent.

Weakness is used to describe knuckling, stumbling, or buckling and sometimes can be characterized by toe-dragging while walking. Weakness may be associated with an upper motor neuron or lower motor neuron lesion. In the case of a lower motor neuron or peripheral nerve injury or illness, the horse shows muscle atrophy and sensory loss. Ataxia is typified by abnormal foot placement and wide swaying of the foot and limb, especially while turning.

The gait abnormalities along with the findings from other parts of the neurologic examination allow the examiner to determine the neuroanatomic site of the problem. The severity of the clinical signs also helps one evaluate the extent or severity of the problem.

One should reexamine horses with an obscure or unusual gait that might be lameness after using local anesthetics to block selected peripheral nerves or following treatment with intraarticular medications. The use of nonsteroidal antiinflammatory drugs for a period of 1 to 2 days also may alleviate pain and help one distinguish between a lameness and a neurologic gait deficit.

One must realize that many horses that have minimal (grade 1 or mild grade 2) deficits often can race or perform other athletic activities.[12] The examining veterinarian has the responsibility of separating a neurologic from a musculoskeletal gait deficit and helping the owner determine the usefulness of the horse. For example, a horse with gait deficits up to grade 3 may be useful as a broodmare or breeding stallion if the horse is handled by careful, knowledgeable persons who understand the risks and have the facilities to accommodate a horse in need of special management. Stallions with this degree of impairment may require assistance when mounting and dismounting mares. If the breed association allows artificial insemination, the stallion may be easier to manage.

10.1.1.2 LOCALIZATION OF THE LESION

At the conclusion of the examination the veterinarian needs to determine if a neurologic abnormality exists and where it is located. If the horse showed no evidence of abnormal behavior, seizures, or abnormal mental status and showed no cranial nerve deficits, the lesion is most likely caudal to the foramen magnum.

The most difficult lesions to localize are in the brainstem, unless the signs include cranial nerve deficits or depression. Horses with brainstem lesions often show signs of weakness and ataxia similar to horses with a lesion in the cervical spinal cord. Two of the most common brainstem lesions in horses involve the seventh and eighth cranial nerves. Vestibular disease or injury may be a sequela of head trauma or an inner ear infection. Facial nerve paralysis may result from trauma to the nerve root origin in the brainstem or where the nerves course along the neck and face to the ears, eyelids, and nares. These problems may occur in horses infected with *Sarcocystis* parasites.

Specific cranial nerve involvement such as head tilt, facial nerve paralysis, or loss of facial sensation can result from trauma, guttural pouch infection, osteomyelitis of the stylohyoid bone, or equine protozoal encephalomyelitis. In addition, cranial nerve deficits may occur with polyneuritis equi and equine motor neuron disease.

Cerebellar lesions are characterized by a failure to blink to bright light, lack of a menace response, and a head tremor that worsens with intentional movements. This disease is an abiotrophy and occurs most frequently in Arabian horses.

Cervical spinal cord disease includes gait and proprioceptive deficits in all four limbs with no signs of brain, brainstem, or cranial nerve deficits. One should note that horses with cervical vertebral stenotic myelopathy may have mild pelvic limb deficits with minimal or barely detectable signs in the thoracic limbs.[15]

Horses with signs of neurologic gait deficits confined to the pelvic limbs have a neuroanatomic localization caudal to T2. When examining a horse with a lesion caudal to T2, carefully checking the tail and anus for involvement of the peripheral nerves or spinal cord segments in this region is important.

Horses that have peripheral nerve injury, equine motor neuron disease, or polyneuritis equi show evidence of 539
weakness, muscle atrophy, and in some cases selected areas of sensory loss. Primary muscle diseases such as 540
exertional rhabdomyolysis, myotonia (congenita or dystrophica), and hyperkalemic periodic paralysis are covered elsewhere in this book. These conditions sometimes can mimic a neurologic problem.

10.1.1.3 DESCRIPTION OF NORMAL GAITS

The reader is reminded that a walk is a natural four-beat gait in the horse. At this gait the normal horse has three feet on the ground at all times. Therefore the walk is a stable gait. Overtracking and interference may occur if the conformation of the horse is abnormal (e.g., with long limbs and a short body) and not as a result of neurologic disease.[10] The trot is also a useful gait to observe when one performs a neurologic examination in the face of subtle gait deficits. In this two-beat symmetric movement the diagonal limbs are in contact with the ground at the same time. If one examines the horse on hard pavement, the trot is the most helpful gait to distinguish a lameness from a neurologic gait deficit. Normally the pace is a gait that results in significant truncal sway as the legs on the same side of the body strike the ground simultaneously. In horses that have neurologic disease, identifying ataxia with truncal sway, which is often accompanied by pacing, is common.

In horses with subtle ataxia, one observes pacing when horses walk with the head held in an extended position. Whenever one observes a horse pacing, the pacing may indicate an underlying neurologic disorder.

The gallop is a high-speed four-beat gait that often seems to be easier to perform than walking in a tight circle or moving at a slow trot. Therefore some horses with a neurologic gait deficit may perform better at high speed. As the horse accelerates or slows down, one may detect abnormalities, and one must observe the horse carefully at this time when an ataxic horse is most unsafe.

Abnormal gaits associated with stringhalt, upward fixation of the patella, and fibrotic myopathy deserve careful attention. Horses that show these gait abnormalities have a mechanical lameness, although the exact cause is unknown and may sometimes be associated with underlying neurologic disease.

Stringhalt often begins as an abrupt onset of excessive flexion of one or both rearlimbs. In some horses the condition may worsen and result in frequent episodes of the foot hitting the abdomen. The condition has been reported for a long time and in some areas of the world may occur as an outbreak.[16] The clinical syndrome is similar to the movement of a horse with a tibial neurectomy with unopposed flexion of the hock and extension of the digit. In the case of Australian stringhalt, the forelimbs and neck muscles may be involved. Stringhalt deserves mention in this chapter because when the examiner observes this gait, the examiner should be certain no other signs of neurologic gait deficits exist. As most readers know, the primary condition usually can be corrected by a tenectomy of the lateral digital extensor tendon, including a portion of the muscle belly. The underlying cause of the disease may be a sensory neuropathy, a myopathy, or primary spinal cord disease. As has been described, the defect likely affects the neuromuscular spindle, as well as the efferent and afferent pathways controlling muscle tone.[9]

Fibrotic myopathy results from scar tissue formation following injury to the semitendinosus and semimembranosus muscles. One may confuse the characteristic foot placement coupled with the abrupt rearward movement of the affected limb with a spastic gait caused by spinal cord injury or disease. With careful examination, a horse suffering from fibrotic myelopathy likely will not go undiagnosed.

Upward fixation of the patella in horses with neurologic disease may result from weakness in the quadriceps muscle group. This weakness is thought to occur because of a lack of use of these muscles or may be caused by abnormal transmission of proprioceptive information to and from the muscles and joint capsule because of damage to the spinal cord.

Horses with profound ataxia often pace when they walk, which often is accompanied by circumduction of the outside rearlimb while turning. These signs suggest general proprioceptive deficits. If the horse has these deficits while walking, observing the horse walking with its head elevated and on a slope is prudent, for these maneuvers often exaggerate a subtle problem.

If the horse shows signs only in the trunk and pelvic limbs, the neuroanatomic localization of the lesion is between T2 and S2 or involves the nerves and muscles of the pelvic limbs. However, the examiner needs to realize that horses with cervical spinal cord lesions often demonstrate signs in the pelvic limbs that are one grade worse than over the thoracic limbs. Therefore a mild cervical spinal cord or brainstem lesion could show minimal or no thoracic limb signs with grade 1 or subtle signs in the pelvic limbs.

Palpating the horse over its back, rump, and muscles of the rearlimbs while being careful to detect any muscle atrophy is helpful. The author routinely stimulates the horse over the side of its body and observes for any twitching of the cutaneous trunci muscles. Such twitching usually is accompanied by a cerebral response and requires a fairly severe lesion to detect areas of analgesia.

A sway reaction performed while the horse is standing and walking is also necessary to assess the pelvic limb strength and proprioceptive functions. In addition, one may evaluate strength by slow but deliberate and forceful pressure along the back and sacral muscles. A normal horse should reflexively arch its back upward, whereas a horse with rearlimb weakness may be unable to withstand this pressure and its rearlimbs may even buckle. 540 541

To complete the neurologic examination, one must examine the tail and anus to determine whether damage has occurred to the sacrococcygeal nerve and muscle segments. A normal perineal reflex results in contraction of the anus and clamping of the tail in response to light stimulation of the skin in this region. Cauda equina neuritis or polyneuritis equi, trauma, and iatrogenic injury resulting from an alcohol tail block are some disorders that may affect this area.

The evaluation of the major peripheral nerves in the horse is also an important part of the neurologic examination. The important points to remember are that damage to a peripheral nerve can result in sensory and motor deficits in the area supplied by the nerve and that focal muscle atrophy follows within a short time after damage to one of these nerves. The examiner is referred to other portions of this book for a more detailed anatomic description of these nerves in the horse; however, a dropped elbow joint with radial nerve paralysis, inability to fix the stifle with femoral nerve paralysis, and atrophy of the supraspinatus and infraspinatus muscles (sweeney) with damage to the suprascapular nerve are classic examples of what to expect with peripheral nerve injuries.[1–3]

10.1.2 Conclusion

To conclude the description of the neurologic examination, the reader is reminded that for a horse to be a good athlete, it must gather information from muscles, tendons, and nerves; process this information in the brain, brainstem, and spinal cord; and relay this information to the musculoskeletal system. The horse must accomplish all of this in a short time to perform complex maneuvers at a high rate of speed. When performing in a setting involving many other horses or when a rider or driver is involved, the horse needs to be able to control these movements in a coordinated fashion to protect itself, other horses, and especially persons. Although for the horse to have every neuron, spinal tract, and glial cell working to be athletic is not necessary, the veterinarian must be able to distinguish between a musculoskeletal lameness and a neurologic condition that may make the horse unsafe for use and dangerous to itself or the rider.

Beyond this, veterinarians must recognize which musculoskeletal and neurologic conditions occur together to assist the prospective buyer better with the decision about whether to purchase the horse. When one recognizes and understands these things, one can determine whether the horse with subtle neurologic gait deficits caused by trauma, infection, or compression may yet be a safe and useful athlete.

10.2

10.2—Cerebrospinal Fluid Evaluation

Frank M. Andrews

541

542

Cerebrospinal fluid (CSF) evaluation has diagnostic importance regarding neurologic disease in horses. Collection and analysis of CSF is indicated to make or confirm a diagnosis of neurologic disease, but this is not without limitations. CSF values may be normal in an animal with severe neurologic deficits because the lesion is extradural, collection occurred early or late in the course of disease, one collected the CSF too far away from the lesion, or the disease involves the ventral roots and peripheral nerve. Even with its limitations, CSF provides valuable information about the central nervous system (CNS). However, one must emphasize that CSF evaluation is another piece of the diagnostic puzzle and together with the history, physical examination, neurologic examination, and other ancillary procedures may help in the diagnosis and prognosis of neurologic disease in horses.

10.2.1

Formation, Flow, and Function of Cerebrospinal Fluid

CSF is an actively transported ultrafiltrate of plasma that bathes the CNS.[1] The CSF is located in the ventricles of the brain and subarachnoid space of the spinal canal (Figure 10.2-1) and originates from the choroid plexus and ependymal lining of the ventricles.[2] CSF flows from the ventricular system up over the cerebral hemispheres and through the subarachnoid space surrounding the spinal cord.[1] Pulsation of blood in the choroid plexuses forces the CSF in a caudad direction. The rate of CSF production varies from 0.017 ml/min in cats to 0.5 ml/min

in human beings[3] and is independent of the blood hydrostatic pressure. The rate of CSF production for horses has not been determined. Osmotic and hypertonic solutions such as mannitol and dimethyl sulfoxide, when added to blood, decrease CSF production and decrease CSF pressure and edema.[1]

Collections of arachnoid villi (arachnoid granulations) are located in the venous sinus or the cerebral vein and absorb CSF. CSF absorption is related directly to the pressure gradient between the CSF and venous sinus. When CSF pressure exceeds venous pressure, these villi act as one-way ball valves forcing CSF flow to the venous sinus.[4]

CSF functions to suspend the brain and spinal cord for protection, regulate intracranial pressure, and maintain the proper ionic and acid-base balance.[1]

10.2.2 Collection of Cerebrospinal Fluid

Techniques for collecting CSF in horses have been described in detail elsewhere.[1–5] One may collect CSF from the lumbosacral site in a standing horse sedated with an intravenous injection of 0.2 to 0.5 mg/kg xylazine or 0.01 to 0.02 mg/kg butorphanol or a combination of both drugs. Alternatively, one can collect CSF from the atlantooccipital site of an anesthetized horse. In foals and recumbent adult horses, one can collect CSF while the animal is restrained and heavily sedated with 1.0 mg/kg xylazine and 0.2 mg/kg butorphanol, both administered intravenously. If the lesion is localized to an area above the foramen magnum (at least cranial to the second cervical vertebra), CSF collected from the atlantooccipital site will be more diagnostic. If the lesion is localized to an area below the foramen magnum (caudal to the second cervical vertebra), CSF collected from the lumbosacral site will be more diagnostic. These differences result from the craniocaudal circulation of CSF. Collecting CSF from both sites at the same time and comparing the findings may be helpful in cases in which neuroanatomic localization of the lesion is difficult.[5]

10.2.3 Examination of Cerebrospinal Fluid

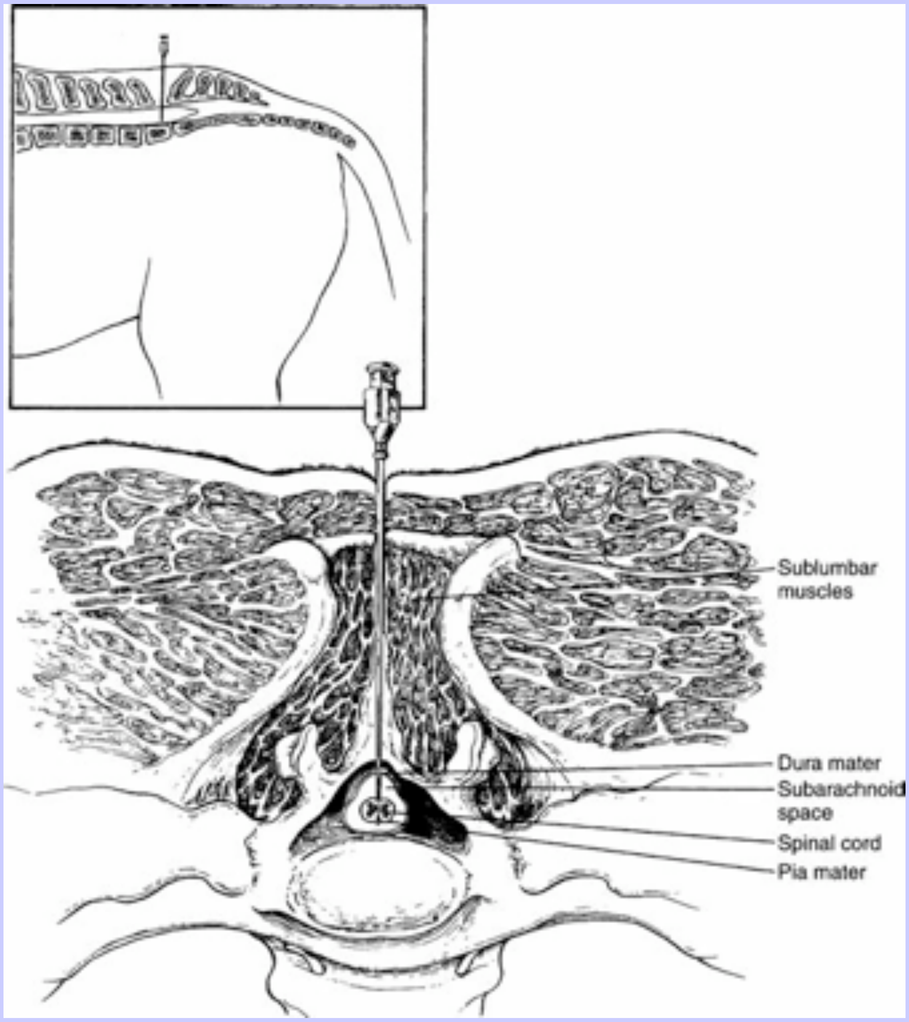
Reference values for CSF in horses have been reported,[6–11] but each laboratory should determine its own reference ranges. CSF determinations that are helpful in evaluating horses with neurologic diseases include pressure, appearance, cellular content, protein concentration (total protein, albumin, immunoglobulin G [IgG]), enzyme activity (creatinine kinase, CK; aspartate aminotransferase; lactate dehydrogenase), and lactic acid concentration.

10.2.3.1 PRESSURE

One can measure opening CSF pressure before withdrawal of CSF by attaching a manometer tube with a three-way stopcock to a properly placed spinal needle, allowing the CSF to rise within.[12] Because the cranial and vertebral cavities are enclosed in a rigid bony compartment, changes in blood pressure or volume can cause a concomitant increase in CSF pressure. Thus increased CSF pressure may occur from venous compression or jugular occlusion. Venous compression causes increased blood volume in the cranial cavity and compression of the CSF space, leading to increased CSF pressure. One can use jugular occlusion clinically to increase CSF pressure and facilitate collection of CSF fluid.[13] The jugular compression maneuver, or Queckenstedt's phenomenon, can help one diagnose compressive lesions, neoplastic lesions, or an abscess along the spinal cord. With compression and obliteration of the subarachnoid space by a 542

compressive lesion in the cervical or thoracic spinal cord, jugular vein compression does not cause a CSF pressure increase in the lumbosacral site.[1] 543

Figure 10.2-1 Lumbosacral spinal fluid collection from a horse showing the various tissue layers that the spinal needle must pass through to obtain a sample. The spinal fluid is collected ventral to the spinal cord in the subarachnoid space. *Inset,* Lateral view of spinal needle placement in the lumbosacral space for collection of cerebrospinal fluid. (From Andrews FM, Adair HS III: Anatomy and physiology of the nervous system. In Auer JA: *Equine surgery*, Philadelphia, 1992, WB Saunders; modified from deLahunta A: Veterinary neuroanatomy and clinical neurology, ed 2, Philadelphia, 1983, WB Saunders.)



Increased CSF pressure may occur following injury, following systemic changes in blood pressure, and in the presence of an intracranial space-occupying mass such as a tumor, abscess, hemorrhage, or edema. One must provide an adequate airway after injury and during surgery to prevent hypoxia-mediated cytotoxic cerebral edema and vasogenic cerebral edema.[14] Cytotoxic edema is caused by inadequate cerebral oxygenation and leads to neuronal, glial, and endothelial cell swelling. Such reactions are especially important during long surgical procedures or recumbency in which respiratory hypoxia and poor alveolar ventilation (hypercapnia) may occur. Hypercapnia increases cerebral blood flow in the cranial cavity and CSF pressure and may worsen existing cerebral edema.[1]

Increased CSF volume may occur in hydrocephalus, which is defined as an increased volume of CSF and can be classified as compensatory or obstructive.[15] Compensatory hydrocephalus is an accumulation of CSF in areas where brain tissue has been destroyed and may occur from brain injury or inflammation. 543
Hydranencephaly is destruction of brain tissue from a viral or other infectious agent and results in severe 544
accumulation of CSF.[15] CSF pressure in compensatory hydrocephalus usually does not increase.[1]

Obstructive hydrocephalus is an accumulation of CSF in the ventricles from an obstruction to CSF outflow or absorption. Cerebral aqueduct malformation may lead to obstruction of ventricular CSF outflow. Inflammatory lesions, especially of the arachnoid villi, result in decreased absorption of CSF and increased CSF pressure. The white matter is affected more severely than the gray matter in obstructive hydrocephalus, but the cerebral cortex usually is spared.[1] CSF pressure in obstructive hydrocephalus usually increases. The presence of an abnormally high opening pressure that drops by 25% to 50% after removing 1 to 2 ml of fluid suggests a space-occupying intracranial mass or spinal cord compression cranial to the site of collection. The removal of more fluid would risk causing tentorial herniation.[12]

10.2.3.2 APPEARANCE

One can evaluate the appearance of CSF immediately after collection. Normal CSF is clear and colorless and does not clot, and newsprint is visible through it.[16] CSF may be red-tinged from blood contamination after a traumatic tap or from preexisting trauma to the CNS. In the case of a traumatic tap, the CSF usually will clear if allowed to flow for several seconds (about 0.5 to 1.0 ml). With preexisting trauma and secondary hemorrhage, the supernatant of CSF after centrifugation is xanthochromic.

Other causes of CSF xanthochromia include increased protein concentration (150 mg/dl)[16] and direct bilirubin leakage from serum in horses with high serum bilirubin concentration. Also, indirect bilirubin may leak across a damaged blood-brain barrier. Clots in the CSF are abnormal and may be caused by increased amounts of fibrinogen resulting from inflammation.[1]

Turbid CSF may indicate an increased number of white blood cells (>200/μl), an increased number of red blood cells (>400/μl), epidural fat, bacteria, fungal elements, or amebic organisms.[1] Cytologic evaluation and cultures can help differentiate causes of turbidity.

10.2.3.3 CYTOLOGIC EVALUATION

One can use a standard hemocytometer to obtain a complete blood count. Also, a sedimentation chamber requiring 0.5 to 1.0 ml of CSF is a rapid method for cytologic evaluation.[17] One must perform cell counts and

cytologic evaluation within 30 minutes to avoid degeneration. If one cannot perform cell counts or cytologic evaluation immediately, then one can mix a portion of the sample with an equal volume of 50% ethanol to preserve cellular characteristics.[12] CSF from normal horses and foals usually contains fewer than 10 white blood cells per microliter. However, much variation occurs in CSF white blood cell counts in horses.[9,10]

No difference are apparent in CSF white blood cell counts in samples taken from the atlantooccipital space.[10] However, one study did show a slightly higher total white blood cell count in CSF taken from the lumbosacral site, but white blood cell counts in all of those horses were less than 10 per microliter.[6]

Small mononuclear cells (70% to 90%) and large mononuclear cells (10% to 30%) predominate in horse CSF. Rarely, one may see neutrophils in horse CSF. Increased CSF large mononuclear phagocytes are visible in horse CSF in diseases of axonal degeneration.[9] One may see increased CSF neutrophil numbers in encephalomyelitis, bacterial meningitis, parasitism, and diseases with extensive inflammation. Occasionally, in severe inflammatory diseases of the neurologic system or parasitism, eosinophils may be visible.[9,17,18] In some cases, cytologic evaluation of CSF may reveal specific etiologic agents causing neurologic disease such as fungal organisms,[16] bacteria, or tumor cells. Although CSF cytologic examination may support a diagnosis of neurologic disease, it may not yield a specific etiologic diagnosis.

10.2.3.4 PROTEIN CONCENTRATION AND COMPOSITION

Normal total protein values range from 20 to 124 mg/dl, depending on the measuring method used[1,6–10] (Table 10.2-1). Total protein concentration is higher in lumbosacral CSF compared with atlantooccipital CSF.[6] A difference of 25 mg/dl of protein between the atlantooccipital and lumbosacral spaces may suggest a lesion closer to the space with greater spinal fluid protein.[10] Proteins in the CSF are derived from the peripheral blood and include albumin, IgG, and possibly other globulins. Increased CSF albumin and IgG concentrations may occur with damage to the blood-brain barrier or increased intrathecal production of IgG. One can determine CSF albumin and IgG concentrations by electrophoresis and radial immunodiffusion, respectively, and can compare these with serum concentrations.[6] Special low-level radial immunodiffusion plates (VMRD, Inc., Pullman, Washington) are available to quantify CSF IgG concentration. One can calculate the albumin quotient ([Albc]/[Albs] × 100) and IgG index ([IgGc]/[IgGs] × [Albs]/[Albc]) to determine blood-brain barrier permeability and intrathecal IgG production.[6] Increased intrathecal IgG production (increased IgG index) may occur in inflammatory spinal cord disease such as equine protozoal myeloencephalitis (EPM), bacterial meningitis, some tumors, and equine motor neuron disease. Increased blood-brain barrier permeability (increased albumin quotient) may occur in equine herpesvirus type 1 following necrotizing vasculitis.[7] 544
Determining blood-brain barrier integrity is also important in planning therapy. If the blood-brain barrier is 545
damaged, pharmacologic agents such as penicillin that do not normally penetrate the blood-brain barrier will penetrate a disrupted blood-brain barrier and attain bactericidal CSF concentration.

TABLE 10.2-1 Cerebrospinal Fluid Values from Atlantooccipital and Lumbosacral Spaces of Normal Healthy Adult Horses[*]

	ATLANTOOCCIPITAL SPACE (MEAN ±SD [RANGE])	LUMBOSACRAL SPACE (MEAN ±SD [RANGE])
Red blood cell count (per μl)	51.0 ±160 (0–558)	36.8 ±59.7 (0–167)
White blood cell count (per μl)	0.33 ±0.49 (0–1)	0.83 ±1.11 (0–3)
Total protein (mg/dl)[*]	87.0 ±17.0 (53 ±11.6)	93.0 ±16.0 (58.0 ±11.0)
	(59–118) (35–74)	(65–124) (39–78)
Albumin (mg/dl)	35.8 ±9.7 (24–51)	37.8 ±11.2 (24–56)
Albumin quotient	1.4 ±0.4 (1.0–2.0)	1.5 ±0.4 (1.0–2.0)
Immunoglobulin G (mg/dl)	5.6 ±1.4 (3–8)	6.0 ±2.1 (3–10)
Immunoglobulin G index	0.19 ±0.046 (0.12–0.27)	0.19 ±0.5 (0.12–0.26)
Creatine kinase (IU/L)	0–8	0–8
Lactate dehydrogenase (IU/L)	0–8	0–8
Aspartate aminotransferase (IU/L)	4–16	0–16
Glucose (mg/dl)	35%-70% of blood glucose	
Lactate (mg/dl)	1.92 ±0.12	2.30 ±0.21
Sodium (mEq/L)	140–150	140–150
Potassium (mEq/L)	2.5–3.5	2.5–3.5

* Total protein concentration next to the mean ±SD in parentheses is the value expected using a total protein standard.

10.2.3.5

ENZYME DETERMINATION

CSF enzyme activity may be increased in neurologic disease. CK and aspartate aminotransferase activity may be increased in diseases with myelin degeneration and neuronal cell damage such as EPM, polyneuritis equi, equine degenerative myelopathy, and equine motor neuron disease. Increased CK activity also may occur in conditions that alter blood-brain barrier permeability, such as equine herpesvirus type 1. In diseases in which the blood-brain barrier is damaged, serum CK can leak into the CSF and increase CSF CK activity. This increased CK activity is not associated with damaged myelin.

Increased CK activity also may suggest other diseases of the CNS. In one study, CK activity (>1 IU/L) most often was associated with EPM in horses and may be helpful in differentiating compressive spinal cord disease from EPM. Furthermore, persistently increased CSF CK activity may be associated with a poor prognosis in horses with EPM.[19] Lactate dehydrogenase activity may be increased in spinal lymphosarcoma.

10.2.3.6

LACTIC ACID CONCENTRATION

CSF lactic acid concentration may be an indicator of neurologic disease (see Table 10.2-1). CSF lactic acid concentration increases in eastern equine encephalomyelitis (4.10 ± 0.6 mg/dl), head trauma (5.40 ± 0.9 mg/dl), and brain abscess (4.53 mg/dl). Lactic acid concentration may be the only CSF parameter increased in horses with brain abscess.[20]

10.2.4

Summary

Normal CSF findings do not always rule out the presence of neurologic disease. CSF values may be normal with lesions outside the CNS not bathed in the CSF, such as extradural, ventral root, and peripheral nerve lesions. Normal CSF values also may occur early or late in the disease process and in CSF samples taken away from the site of the lesion. Acute neurologic disease, especially if multifocal, may not have sufficient time to cause significant damage to the blood-brain barrier and alter CSF constituents, whereas in chronic CNS disease the blood-brain barrier may be repaired and functional but with nervous tissue replaced by fibrous tissue. Fibrosis of nervous tissue may result in significant neurologic gait deficits and normal CSF constituents. CSF taken away from the site of the lesion shows normal findings despite significant neurologic gait deficits. For example, CSF in a horse with a cervical spinal cord abscess may show a suppurative inflammation in the lumbosacral CSF and a normal atlantooccipital CSF. This discrepancy is caused by the caudad flow of CSF.

CSF may be helpful in supporting the diagnosis of neurologic disease in horses and is part of the diagnostic workup. Because CSF evaluation is an ancillary diagnostic test, one should use it with, and not as a substitute 545
for, a thorough history, physical examination, neurologic examination, and other diagnostic tests. 546

10.3

10.3—Electrodiagnostic Aids and Selected Neurologic Diseases

Frank M. Andrews

Localizing lesions to and within the nervous system can be difficult in some cases using only clinical and neurologic examinations. Generally, neurologic disease is characterized by changes in cell electric activity; because electric activity has amplitude and frequency, one can measure it by electronic equipment. The observed electric activity may be helpful in defining and localizing lesions of the nervous system.

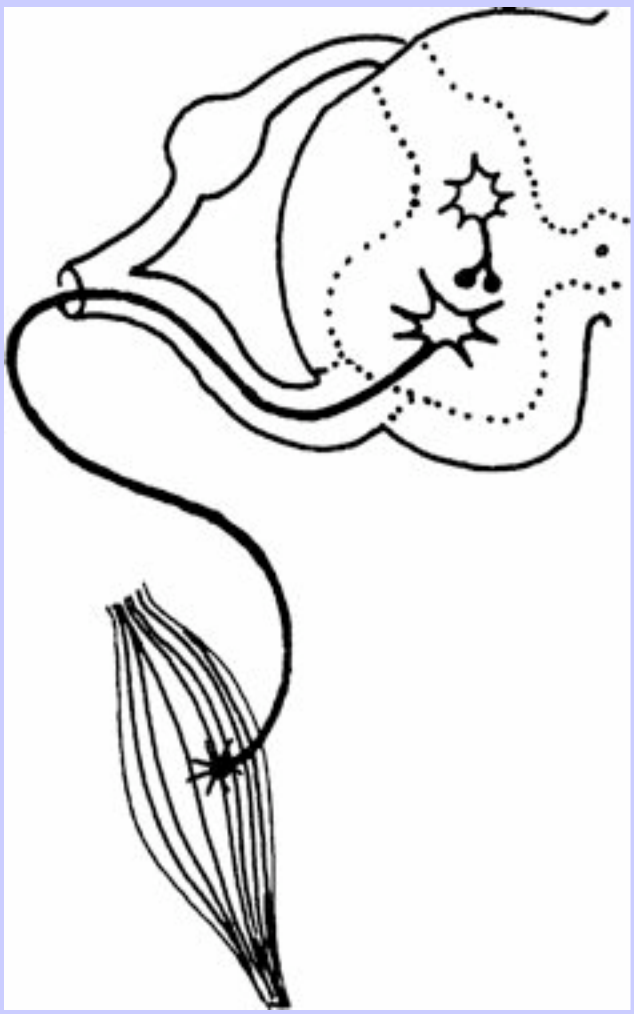
Electromyography (EMG), auditory brainstem response (ABR) testing, and electroencephalography (EEG) are electrodiagnostic aids that may be helpful in the localization, diagnosis, and prognosis of neurologic disease in horses. Needle EMG and nerve conduction studies are helpful in localizing and defining diseases of the lower motor neuron or motor unit. ABR testing is helpful in localizing lesions to cranial nerve VIII and auditory pathways along the brainstem. EEG is helpful in diagnosing focal and diffuse intracranial lesions. Use of these diagnostic aids as an extension of the neurologic examination, separately or collectively, can provide valuable information about nervous system function and help in diagnosing neurologic disease. These techniques are noninvasive and in many cases can be done on the awake horse with mild sedation. Even when these techniques do not provide the information necessary to arrive at a diagnosis, they may provide a more complete understanding of the disease process.

10.3.1 Electromyography

Needle EMG is the graphic recording of muscle cell electric activity during contraction or at rest from a recording electrode placed in the muscle. Electric activity is recorded by means of an amplifier on an oscilloscope.[1–3] Nerve conduction studies consist of stimulating a peripheral nerve with electric current and recording the resultant physiologic electric activity from other segments of the nerve or from the muscles innervated by those nerves.[4] Together, EMG and nerve conduction studies may help in the localization, diagnosis, and prognosis of diseases of the lower motor unit. The motor unit consists of the ventral horn cell bodies (located in the ventral horn of the spinal cord), its axon, the peripheral nerve, the myoneural junction, and the muscle fibers it innervates (Figure 10.3-1). 546

547

Figure 10.3-1 Illustration of the motor unit, including the ventral horn cell in the spinal cord, ventral root, peripheral nerve, neuromuscular junction, and muscle.



10.3.1.1 ELECTROMYOGRAPHIC EXAMINATION

A history and physical and neurologic examination always should precede the EMG examination; these aid in localizing the lesion, shorten the examination time, and minimize trauma to the horse. Initially, one examines the standing horse that is under mild sedation. One can tranquilize the horse with 0.2 to 0.5 mg/kg xylazine administered intravenously or 0.2 to 0.5 mg/lb xylazine and 2 to 10 mg butorphanol administered intravenously. Examination of the awake horse aids in evaluating individual motor unit action potentials (MUAPs), summated MUAPs, and interference pattern. One can evaluate normal and abnormal MUAPs and measure their amplitudes. Unfortunately, in the awake horse an interference pattern (many MUAPs) sometimes can obscure abnormal low-amplitude EMG potentials. In this case, further examination may require general anesthesia.

In the needle EMG examination, one should thrust the exploring electrode briskly into the muscle and hold it until the animal completely relaxes. To enable relaxation, one can force the animal to bear weight on the opposite limb. Once relaxation has occurred, one can evaluate the resting activity or any postinsertional activity of the muscle. One should evaluate at least four areas and depths of smaller skeletal muscles and six to eight areas and depths of larger skeletal muscles when possible. One should examine the horse systematically so as not to miss a lesion. One can perform needle EMGs in many of the major extrinsic muscles of the horse (Table 10.3-1). One also can perform needle EMGs on facial, laryngeal, esophageal, pectoral, and external anal sphincter muscles when indicated by neurologic examination. One may perform nerve conduction studies and collect muscle biopsy specimens to define suspected lesions further or confirm a diagnosis.

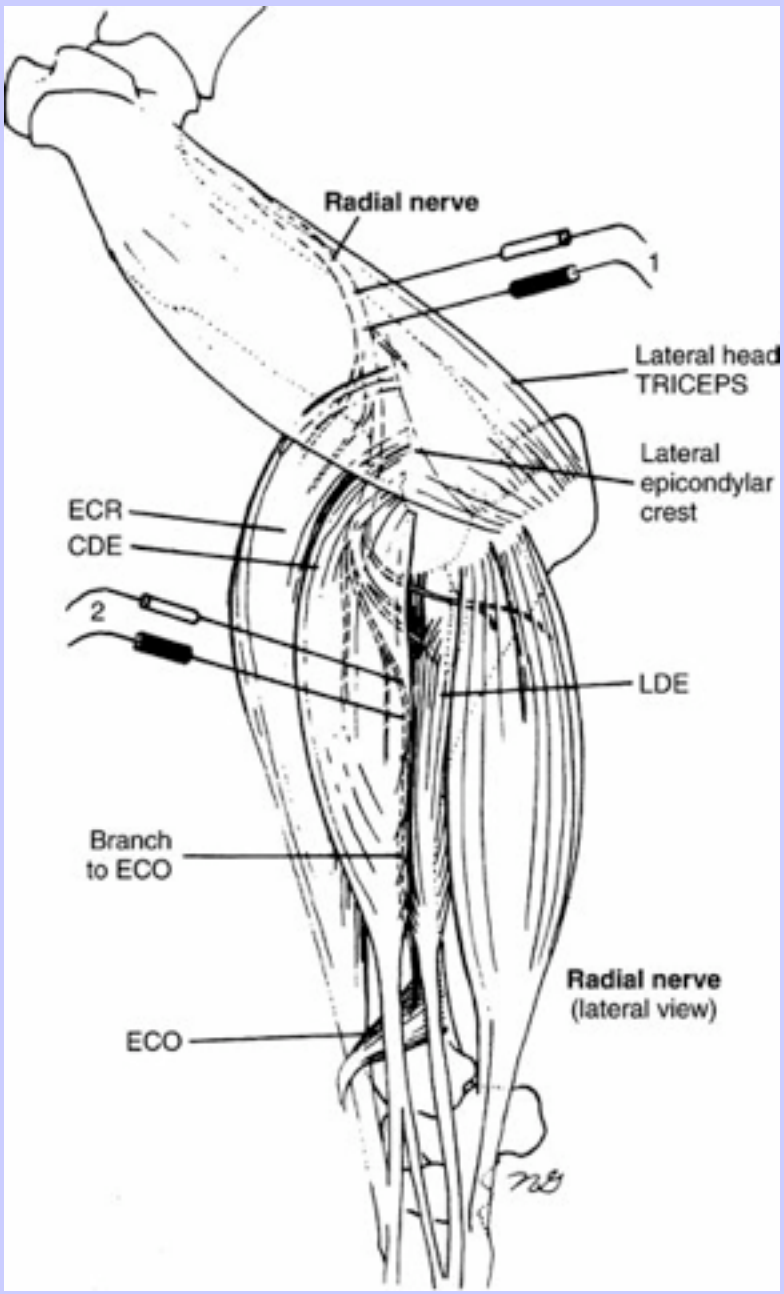
TABLE 10.3-1 Muscles, Nerves, and Nerve Roots Evaluated During Routine Electromyographic Examination of Horses

MUSCLES	PERIPHERAL NERVE	SPINAL NERVE ROOT
REAR LIMB		
Long digital extensor	Peroneal nerve	L6-S1
Gastrocnemius	Tibial nerve	S1-S2
Deep digital flexor	Tibial nerve	S1-S2
Semimembranosus	Ischiatic nerve	L5-S2
Vastus lateralis	Femoral nerve	L3-L5
Biceps femoris	Caudal gluteal, ischiatic, and peroneal nerves	L6-S2
Middle gluteal	Cranial and caudal gluteal nerves	L5-S2
PARAVERTEBRAL		
Paravertebral muscles (segmentally)	Dorsal branches of ventral spinal nerves (L6-C1)	L6-C1
THORACIC LIMB		
Subclavius	Pectoral nerve	C6-C7, T1
Supraspinatus	Suprascapular nerve	C6-C8
Infraspinatus		
Deltoideus	Axillary nerve	C6-C8
Biceps brachii	Musculocutaneous nerve	C6-C8
Triceps	Radial nerve	C7-T1
Extensor carpi radialis	Radial nerve	C7-T1
Superficial digital flexor	Ulnar nerve	C8-T2
Deep digital flexor	Ulnar and median nerve	C7-T1, T2

10.3.1.2 NERVE CONDUCTION STUDIES

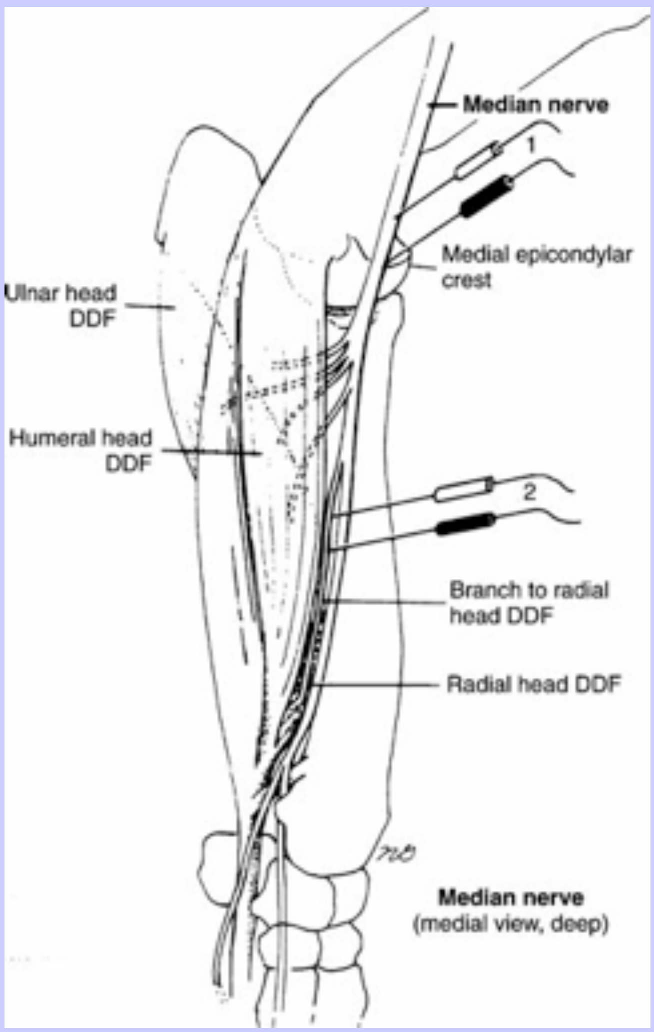
The evaluation of nerve conduction velocities requires knowledge of the topographic anatomy of nerves and muscles, plus a stimulator capable of delivering up to 150 V at durations of 0.1 to 3 ms at variable frequencies, up to 100 Hz. Most standard EMGs have built-in stimulators with adequate parameters to do nerve conduction studies. One can locate the peripheral nerve to be assessed by palpation or by anatomic landmarks and then can stimulate it. One can palpate or observe the resultant muscle contraction and can view the evoked muscle action potential, which has a thumping sound, on the oscilloscope. 547

Figure 10.3-2 Illustration of anatomy and electrode placement used in radial nerve conduction velocities. *ECR,* Extensor carpi radialis; *CDE,* common digital extensor; *LDE,* long digital extensor; *ECO,* extensor carpi obliquus. (From Henry RW, Diesem CD, Wiechers MD: Evaluation of equine radial and median nerve conduction velocities, *Am J Vet Res* 40:1406-1410, 1979.)



Nerve conduction studies are difficult to do in horses and therefore are not done routinely. However, the technique for radial and median nerve conduction studies in the horse has been reported.[5,6] One must perform nerve conduction studies with the horse under general anesthesia and may use them to evaluate the speed of conduction of large myelinated motor nerves. One should place the horse in lateral recumbency with the affected side up. One stimulates the appropriate motor nerve by monopolar needle electrodes inserted at or near the nerve and records an evoked MUAP from an innervated muscle (Figures 10.3-2 and 10.3-3). One may see or palpate the contraction of appropriate muscles and insert needle electrodes until one obtains a repeatable response. One may use the unaffected limb as a control.

Figure 10.3-3 Illustration of anatomy and electrode placement used in median nerve conduction velocities. *DDF,* Deep digital flexor. (From Henry RW, Diesem CD, Wiechers MD: Evaluation of equine radial and median nerve conduction velocities, *Am J Vet Res* 40:1406-1410, 1979.)



In horses, one can obtain radial nerve recordings from the extensor carpi radialis and abductor digiti longus (extensor carpi obliquus) muscles (see Figure 10.3-2) and can obtain median nerve recordings from the humeral and radial heads of the deep digital flexor tendon[5,6] (see Figure 10.3-3). One can obtain facial nerve recordings from the levator nasolabialis muscle by stimulating the buccal branch of the facial nerve just ventral to the facial crest.[7] Usually one can obtain a supramaximal stimulus at 70 to 90 V for 0.1-ms duration. Nerve conduction studies are helpful in diagnosing radial nerve, median nerve, and possibly facial nerve injury. 548

549

10.3.2 Normal Electromyographic Potentials

Normally occurring EMG potentials and nerve stimulation studies are described next. One can examine the muscle at rest, under submaximal contraction, maximal contraction, and following direct nerve stimulation.

10.3.2.1 INSERTIONAL ACTIVITY

Insertional activity consists of short bursts of high-amplitude, moderate- to high-frequency (<200 Hz) electric activity following insertion or movement of the exploring electrode in the muscle (Figures 10.3-4 and 10.3-5). In normal skeletal muscle this activity stops a few milliseconds following cessation of needle movement. Insertional activity may be caused by mechanical stimulation, muscle fiber injury,[3,8,9] or depolarization of muscle fibers directly adjacent to the EMG needle.[1] Positive sharp waves and fibrillation potentials observed during or associated with needle insertion that stop after cessation of needle movement are considered normal. Damage to muscle fibers by needle insertion is probably the source of these potentials. However, positive sharp waves and fibrillation potentials persisting after needle insertion are considered abnormal and may suggest early muscle denervation.[3]

10.3.2.2 RESTING ACTIVITY (POSTINSERTIONAL BASELINE)

Resting activity is observed in relaxed muscle and is characterized by electric silence. A flat line appears on the oscilloscope. When the needle comes to rest near a nerve twig or end plate, the needle may irritate small intramuscular nerve terminals, which results in the production of two characteristic potentials, end-plate noise and end-plate spikes. End-plate noise produces a rippling of the baseline and a low-pitched continuous noise (Figure 10.3-6). End-plate spikes, on the other hand, are high-amplitude intermittent spikes and make a popping sound. End-plate noise and spikes can occur alone or together. The origin of end-plate noise is thought to be extracellularly recorded miniature end plate potentials,[10,11] whereas end-plate spikes are thought to be single muscle fiber contractions following needle electrode irritation of the nerve terminals.[11] In human beings these potentials are associated with dull pain,[3] and repositioning the needle often eliminates their activity.

Figure 10.3-4 Normal insertional activity in the infraspinatus muscle. Gain: 0.500 mV/division; time: 10 ms/division.

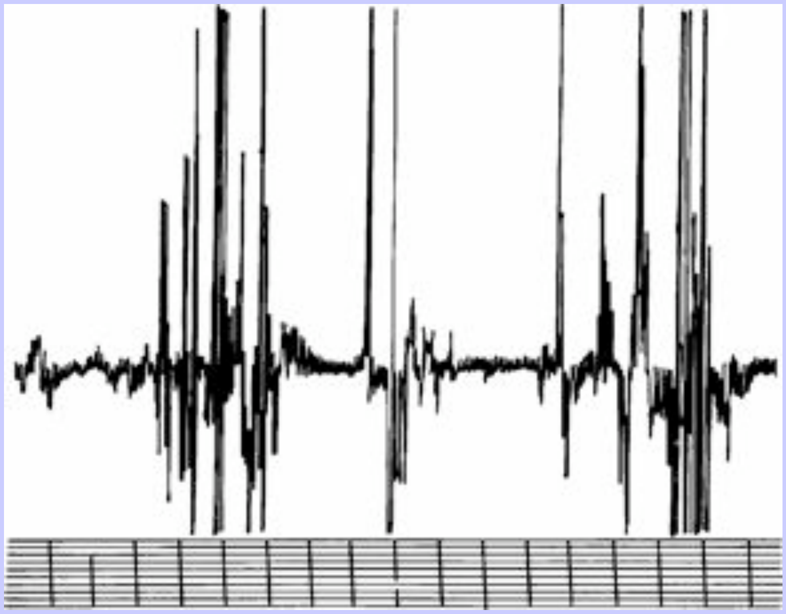


Figure 10.3-5 Electromyograph of the middle gluteal muscle showing normal resting activity *(arrowheads)*, fasciculation potentials *(A, E, G)*, fibrillation potentials *(C)*, positive sharp waves *(B, F)*, and a small motor and action potential *(D)*.

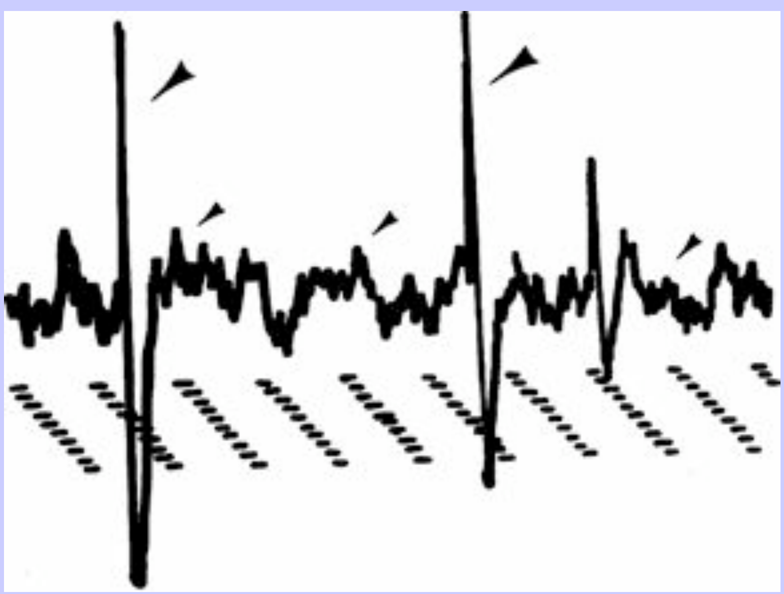
10.3.2.3 MOTOR UNIT ACTION POTENTIALS

MUAPs are voluntary or reflex muscle contractions observed after insertion of the needle electrode. They represent the sum of a number of single muscle fiber potentials belonging to the same motor unit. MUAPs are usually mono-, bi-, and triphasic. Because individual muscle fibers fire nearly synchronously, the prefixes refer to the number of phases above and below the baseline (see Figure 10.3-5). A few polyphasic potentials (greater than four phases) may occur in normal muscle but usually do not exceed 5% to 15% of the population of MUAPs observed.[3] MUAPs have an amplitude ranging from 500 to 3000 μV and a duration ranging from 1 to 15 ms. Examination of the awake horse enhances the evaluation of the amplitude and number of phases of MUAPs in the muscle.

One may see these MUAPs when one forces the animal to bear weight on or retract a limb, resulting in contraction of that explored muscle. In lightly stimulated muscle, one may see single MUAPs, as single motor
units are recruited (see Figure 10.3-5). As muscle contraction becomes more intense, more motor units are 549
recruited, and the greater frequency of MUAPs appears on the oscilloscope. Once MUAPs fill the screen, one 550
observes an interference pattern. Clinically, the number of phases and the duration of MUAPs are of greater importance than amplitude, because amplitude may be influenced by species, the muscle explored, the age of the horse, and electrode position.[9] Furthermore, MUAP duration has been shown to increase with age in human beings.[12]

Figure 10.3-6 Electromyograph from triceps brachii muscle showing end-plate spikes *(large arrowheads)* and end-plate noise *(small arrowheads)*. Gain: 0.500 mV/stairstep; time: 10 ms/division.

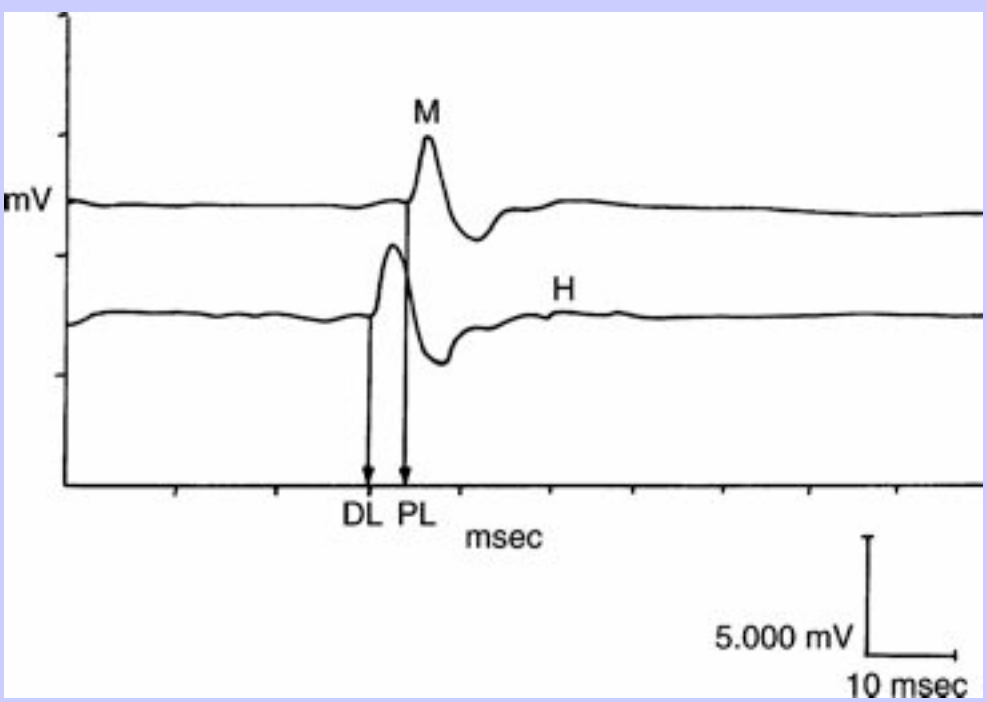


10.3.3

Evoked Muscle Potentials

Stimulation of a mixed motor and sensory nerve results in two observed potentials: the direct evoked muscle action potential (M wave) and the reflex evoked muscle action potential (H wave). The M wave is the direct muscle action potential resulting from orthodromic conduction of direct nerve stimulation (Figure 10.3-7). The M wave is the most commonly used potential in veterinary medicine. This wave is usually biphasic or triphasic and is larger than the H wave. The amplitude of these evoked potentials depends on the number of motor units activated and on the size of the muscle, predominant fiber type, and type of recording electrode used.[4] With monopolar electrodes, amplitudes observed in the horse range from 5 to 60 mV for a 2- to 10-ms duration. Normal amplitudes and durations have been reported for several muscles in the horse. The time required for the potential to travel down the motor nerve, cross the neuromuscular junction, travel down the muscle membrane, and stimulate a response in the muscle is called the latency. When two points along the motor nerve are stimulated, one can measure the distance between the stimulating electrodes (in millimeters) and divide it by the difference in latencies (in milliseconds). Normal median and radial nerve conduction velocities are 60 to 80 m/sec.[5,6] Normal facial nerve conduction velocities are 55 to 70 m/sec.[7]

Figure 10.3-7 Evoked muscle action potentials from the levator nasolabialis muscle after direct stimulation of the buccal branch of the facial nerve illustrating the M wave and H wave. Nerve conduction velocity: 66.0 m/sec. *DL,* Distal latency; *PL,* proximal latency.



10.3.4 Abnormal Electromyographic Potentials

Spontaneous activity in a relaxed muscle after cessation of needle movement may be clinically significant. Diseases affecting the motor unit can lead to altered muscle electric activity, such as prolonged or decreased insertional activity, postinsertional activity, altered waveforms, and complex repetitive discharges. Some abnormal EMG potentials are described next.

10.3.4.1 PROLONGED OR DECREASED INSERTIONAL ACTIVITY

Prolonged electric activity continuing 1 to 10 ms after needle insertion and placement in the muscle is considered abnormal and probably is caused by hyperirritability and instability of the muscle fiber membrane.[9] This activity is most prominent 4 to 5 days after denervation in dogs.[13] Increased or prolonged insertional activity usually precedes the onset of other denervation potentials (fibrillation potentials and positive sharp waves) and may suggest early denervation atrophy.[9] However, one also may see prolonged insertional activity in myotonic disorders and myositis.[13]

Decreased insertional activity (decreased amplitude, duration, or both) may be associated with a decreased number of functioning muscle fibers and may suggest a long-standing neuropathy or myopathy. Infiltration of connective tissue and fat in the muscle can lead to a decreased number of muscle fibers, which can decrease
insertional activity. Complete fibrosis of the muscle may result in loss of insertional activity. Insertional 550
activity also may be absent when muscle fibers are functionally inexcitable, as occurs during attacks of 551
familial periodic paralysis,[3,14] if one uses a faulty needle electrode, or if the EMG needle comes to rest in a normal muscle.[3]

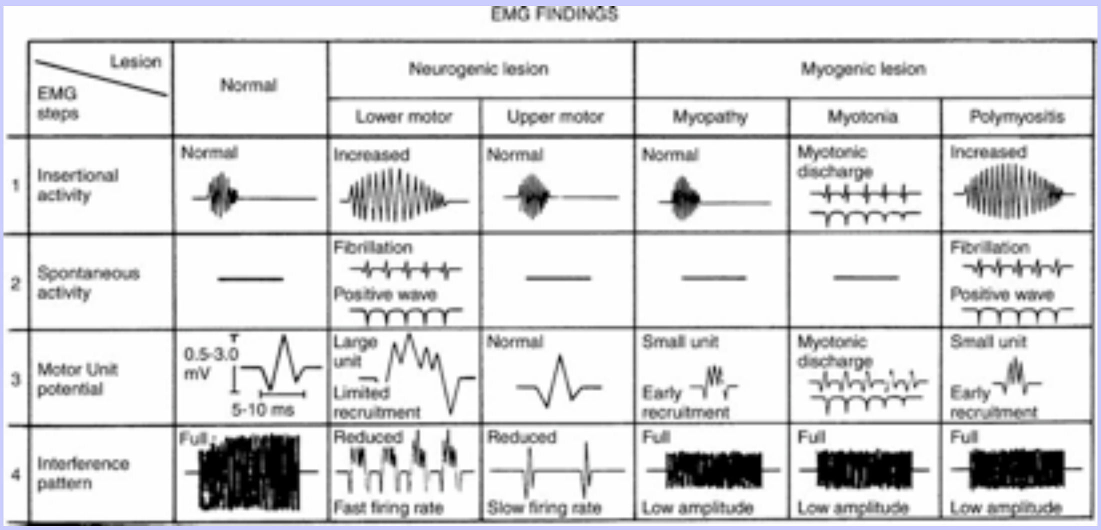
10.3.4.2 POLYPHASIC MOTOR UNIT ACTION POTENTIALS

Polyphasic MUAPs (myopathic potentials) have increased frequency (greater than four phases) and decreased amplitude and duration (Figure 10.3-8), which one observes during submaximal muscle contraction and which result from an increased number of action potentials for a given strength of contraction. Myopathic potentials result from a diffuse loss of muscle fibers[15] and indicate the need for extra motor units to perform the work normally done by fewer motor units.[16] Myopathic potentials are polyphasic and most often occur in primary myopathies such as myotonia-like syndromes, periodic paralysis, myositis, botulism, and myasthenia gravis–like syndromes. These potential also have been reported in steroid-induced myopathies, Cushing's syndrome, and membrane defect myopathies.[9]

10.3.4.3 NEUROPATHIC MOTOR UNIT ACTION POTENTIALS

Neuropathic potentials are MUAPs of decreased frequency and longer duration than myopathic potentials and may occur during minimal and maximal muscle contraction (see Figure 10.3-8). Thus one observes fewer MUAPs of increased amplitude than expected for the strength of contraction, which is more noticeable during maximal contraction and produces a sputtering or motorboat sound. Neuropathic potentials probably are caused by a decreased number of functioning axons firing during maximal muscle contraction. These potentials are most often present in primary neuropathies in which collateral reinnervation has occurred.[16]

Figure 10.3-8 Differential electromyographic findings in neurogenic and myogenic conditions. (Modified from Kimura J: *Electrodiagnosis in diseases of nerve and muscle: principles and practice,* Philadelphia, 1984, FA Davis.)



10.3.4.4 FIBRILLATION POTENTIALS

Fibrillation potentials are the most commonly observed abnormal spontaneous electropotential in EMG (see Figure 10.3-5). These spontaneous discharges sound like frying eggs, crinkling cellophane, or frying bacon and have an initial positive deflection of 100 to 300 μV in amplitude and 2 to 4 ms in duration. They are diphasic or triphasic in waveform. Fibrillation potentials strongly suggest denervation but have been observed in polymyositis, muscular dystrophy, and botulism. Their origin is uncertain, but fibrillation potentials are thought to be spontaneous discharges from acetylcholine-hypersensitive denervated muscle fibers[1,17] or may result from muscle necrosis,[18] muscle inflammation, and focal muscle degeneration. A few fibrillation potentials have been observed in normal healthy muscle, but they are usually not reproducible in other areas of the muscle.

The onset of fibrillation potentials following denervation depends on the size of the animal. The larger the 551
animal, the later the onset of fibrillation potentials[19]; they have been reported between days 5 and 16 552
postdenervation in dogs[20] and human beings.[18] The author has observed fibrillation potentials 4 to 10 days after nerve injury in horses. Fibrillation potentials often occurred along with positive sharp waves; they increase and then decrease in amplitude as the muscle atrophies, with activity ceasing on complete muscle atrophy. Fibrillation potentials occurring alone denote a more severe disease process than the presence of positive sharp wave potentials alone.[17] Fibrillation potentials are helpful in evaluating the length of time muscle denervation has been present and are important in diagnosing denervation before clinical muscle atrophy. One also can use fibrillation potentials as a prognostic indicator: by monitoring fibrillation frequency and amplitude changes with serial examinations, one can assess the extent and progress of denervation. Also, a

decrease in fibrillation potentials followed by the recording of MUAPs may indicate reinnervation and may suggest a favorable prognosis.[18]

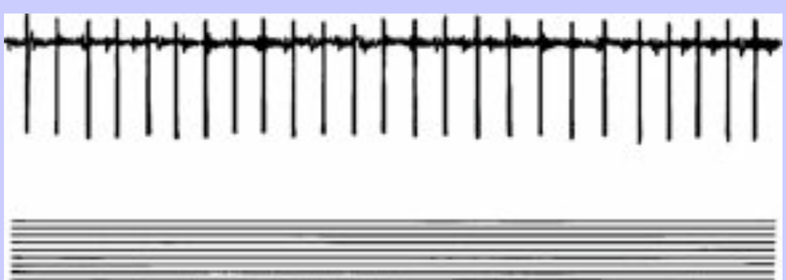
10.3.4.5 POSITIVE SHARP WAVES

Positive sharp waves are potentials in which the primary deflection is downward, followed by a lower-amplitude, longer-duration negative deflection (see Figure 10.3-5). This waveform has been described as resembling a saw tooth.[3] Positive sharp waves occur with muscle denervation and muscular diseases such as myositis, exertional rhabdomyolysis (tying-up syndrome),[21] and spinal shock.[16] Sometimes one observes positive sharp waves in association with or shortly after insertional activity that persist after electrode placement. More than two positive sharp waves occurring after insertional activity may indicate early denervation. Positive sharp waves may occur in denervated muscle following chronic exertional rhabdomyolysis, myotonia,[21] equine protozoal myeloencephalitis (EPM), laryngeal hemiplegia,[22] suprascapular nerve injury (sweeney),[23] and compressive myelopathies. Positive sharp waves often precede or appear along with fibrillation potentials in denervated muscle. One can observe these potentials singly or in trains (Figure 10.3-9), and they may sound like a machine gun. The origin of positive sharp waves is uncertain but may be associated with hyperexcitable muscle cell membranes.[17]

10.3.4.6 FASCICULATION POTENTIALS

Fasciculation potentials are spontaneous discharges from a group of muscle fibers representing the whole or part of a motor unit[3,17] (see Figure 10.3-5). The source of fasciculation potentials has not been determined yet, but evidence suggests they originate from neural discharges in the spinal cord or along the peripheral nerve.[24,25] Fasciculation potentials occur in diseases of anterior horn cells and irritative-type lesions of root or peripheral nerve, such as radiculopathies and nerve entrapments in human beings.[13] Little significance is placed on isolated fasciculation potentials in horses. However, fasciculation potentials in the presence of fibrillation potentials or positive sharp waves may indicate lower motor neuron disease and may occur in suprascapular nerve entrapment (sweeney) in horses.

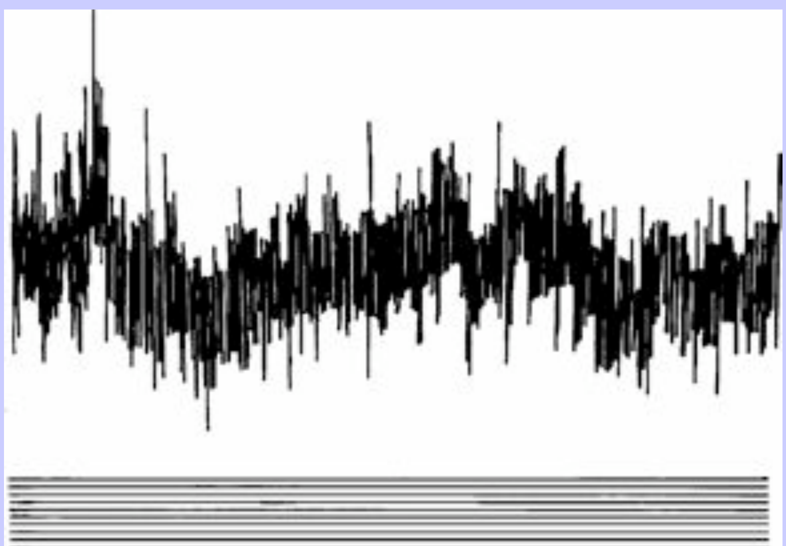
Figure 10.3-9 Electromyograph showing train of positive sharp waves. Gain: 500 V/stairstep.



10.3.4.7 COMPLEX REPETITIVE DISCHARGES VERSUS MYOTONIC POTENTIALS

Complex repetitive discharges (bizarre high-frequency potentials) and myotonic potentials occur less frequently in horses. Both of these potentials are repetitive MUAPs induced by insertion of the needle electrode or percussion of muscle. Bizarre high-frequency potentials tend to be shorter in duration and end abruptly compared with myotonic discharges. Bizarre high-frequency potentials sound like a machine gun. However, myotonic potentials often wax and wane in amplitude, last 4 to 5 seconds[2,3,9] and sound like a dive-bomber, hence the nickname "divebomber potential"[1,9] (Figure 10.3-10). Myotonic and bizarre high-frequency potentials are thought to be associated with hyperexcitability of the muscle cell membrane.[1] Bizarre high-frequency potentials may occur in diseases of the lower motor unit such as muscular dystrophy,[1,9,21] 552 steroid-induced myopathy,[9] polymyositis, chronic denervation,[26] and hyperkalemic periodic paralysis.[14] 553 Myotonic potentials may occur in myotonia congenita and myotonia dystrophica[21] and may occur in hyperkalemic periodic paralysis in human beings, which may reflect abnormal muscle chloride or potassium conductance.[3] Myotonic potentials also have been observed in horses with hyperkalemic periodic paralysis, but some were obscured by concurrent complex repetitive discharges.[14]

Figure 10.3-10 Electromyograph showing waxing and waning myotonic potentials. Gain: 500 V/stairstep.



10.3.5 Diseases Affecting the Motor Unit and Peripheral Nerves

Diseases of the motor unit and peripheral nerves can lead to changes in skeletal muscle electric activity or nerve conduction velocity or both. In these diseases EMG may be a useful diagnostic aid in localizing the lesion.

10.3.5.1 FOCAL AND MULTIFOCAL MYELOPATHIES

Compressive cervical myelopathies, cervical stenotic myelopathy (wobbler syndrome), and EPM are common causes of neurologic signs in the horse. These conditions are characterized by damage to the sensory pathways and in some instances damage to the ventral horn cells of the spinal cord, a component of the motor unit. Physical examination may reveal muscle atrophy and sweating over affected muscles. Needle EMG of the cervical axial musculature in horses presented with truncal, forelimb, and hindlimb ataxia, without cranial nerve deficits, may reveal increased insertional activity, fibrillation potentials, and positive sharp waves indicating compression of the ventral horn cells or ventral roots.[27] Abnormal postinsertional activity at the level of the spinal cord compression may allow the clinician to focus the radiographic examination.

In cases of EPM, needle EMG may reveal fibrillation potentials, positive sharp waves, and abnormal insertional activity in affected limb muscles in horses presented for obscure lameness. One also can examine horses with muscle asymmetry (Figure 10.3-11) via needle EMG to determine the extent of muscle involvement. The examination may lead to early diagnosis of EPM so that one can prescribe treatment. Serial needle EMG examination also may be helpful in monitoring the response to treatment and prognosis.

10.3.5.2 RADIAL AND SUPRASCAPULAR NERVE INJURY

Damage to the peripheral nerves leads to muscle atrophy of the innervated muscle. Damage to the radial and suprascapular nerves can occur with trauma to the cranial aspect of the shoulder. Needle EMG and nerve conduction studies are helpful in evaluating the extent of damage to these and other peripheral nerves. Needle EMG and nerve conduction studies also may be able to differentiate lost or reduced limb function caused by nerve damage from painful conditions. Muscle groups that have atrophied because of disuse (disuse atrophy) caused by a painful condition show no postinsertional activity on needle EMG examination.

Figure 10.3-11 Horse with gluteal muscle atrophy following protozoan myelitis showing distribution of abnormal electromyographic potentials.

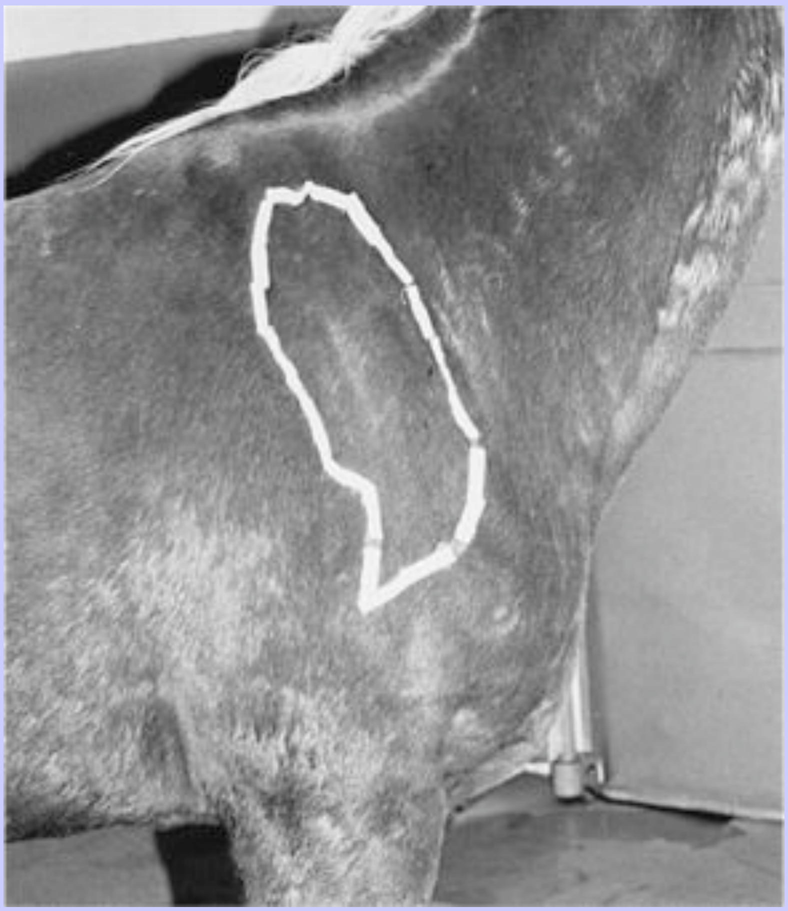
Positive sharp waves and fibrillation potentials in the triceps brachii and extensor carpi radialis muscles may suggest radial nerve injury. Positive sharp waves and fibrillation potentials in the supraspinatus and infraspinatus muscles may suggest suprascapular nerve injury (Figure 10.3-12). Postinsertional activity in these muscle groups and the lateral head of the triceps suggests damage to the brachial plexus (Figure 10.3-13). Thus needle EMG may be helpful in differentiating suprascapular nerve injury from brachial plexus injury. Visible evidence of muscle atrophy may not be present until several weeks after injury. To confirm a radial nerve injury, one can calculate the radial nerve conduction velocity (Figure 10.3-14). If the nerve conduction velocity is less than 60 m/sec or significantly less than the opposite limb, one may suspect radial

nerve injury. Radial nerve injury also may lead to a decreased amplitude and duration of the evoked muscle action potential.

Needle EMG and nerve conduction studies may also be helpful in determining success of nerve decompression surgery. Once the nerve is decompressed surgically, serial needle EMG examinations may be helpful in determining if permanent nerve damage has occurred and the extent of return of nerve function. 553

554

Figure 10.3-12 Horse with suprascapular nerve injury with characteristic electromyographic distribution of fibrillation potentials and positive sharp waves in supraspinatus and infraspinatus muscles.



10.3.5.3

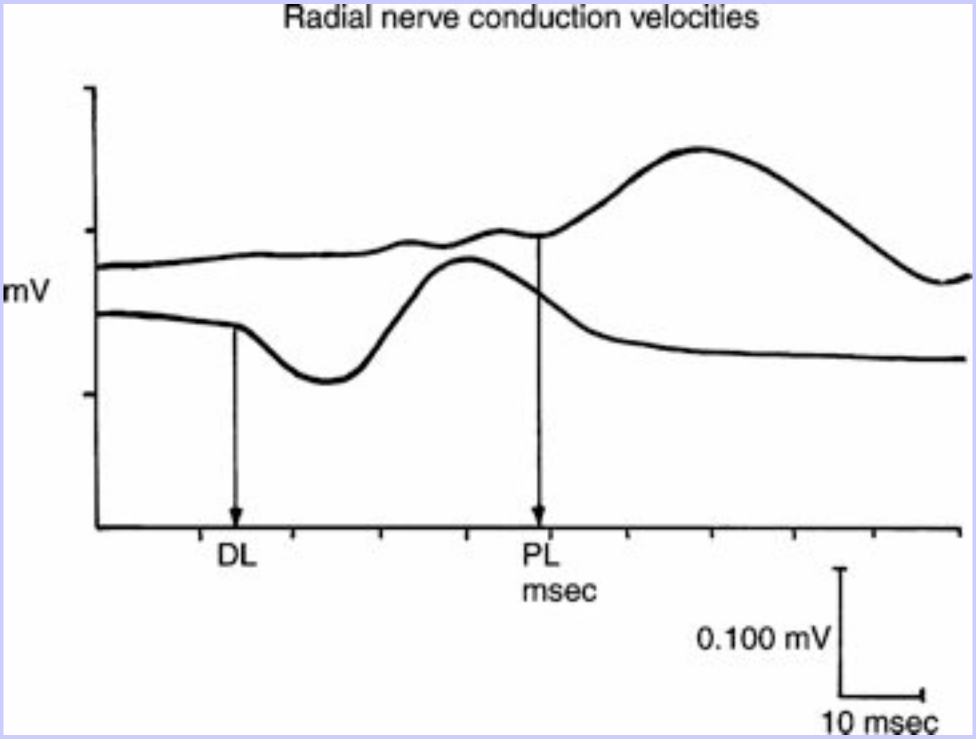
LARYNGEAL HEMIPLEGIA

Laryngeal hemiplegia has been described extensively in the literature as denervation of the intrinsic laryngeal musculature, specifically the recurrent laryngeal nerve.[5] One difficulty with this condition is that current diagnostic techniques (endoscopy, inspiratory stridor with exercise) are limited to recognizing laryngeal hemiplegia after onset of clinical signs.[28] However, fibrillation potentials and positive sharp waves in the

dorsal cricoarytenoid muscle on needle EMG examination may appear before clinical signs. Thus needle EMG may be useful in the early detection of laryngeal hemiplegia in horses. Spontaneous EMG activity, including fibrillation potentials, positive sharp waves, or bizarre high-frequency discharges, have been reported in the dorsal cricoarytenoid muscle of horses affected with laryngeal hemiplegia. Fibrillation potentials and positive sharp waves are the most common abnormal electric potential observed in horses with laryngeal hemiplegia. Decreased insertional activity and bizarre high-frequency discharges were reported at a lesser frequency.[22]

Figure 10.3-13 Horse with brachial plexus injury showing characteristic distribution of electromyographic charges, including fibrillations and positive sharp waves. The involvement of the supraspinatus, infraspinatus, triceps brachii, extensor carpi radialis, and pectoral muscles is notable.

Figure 10.3-14 Evoked muscle action potential from the extensor carpi radialis muscle showing decreased amplitude and decreased nerve conduction velocity, suggesting radial nerve injury. *DL,* Distal latency; *PL,* proximal latency.



10.3.5.4

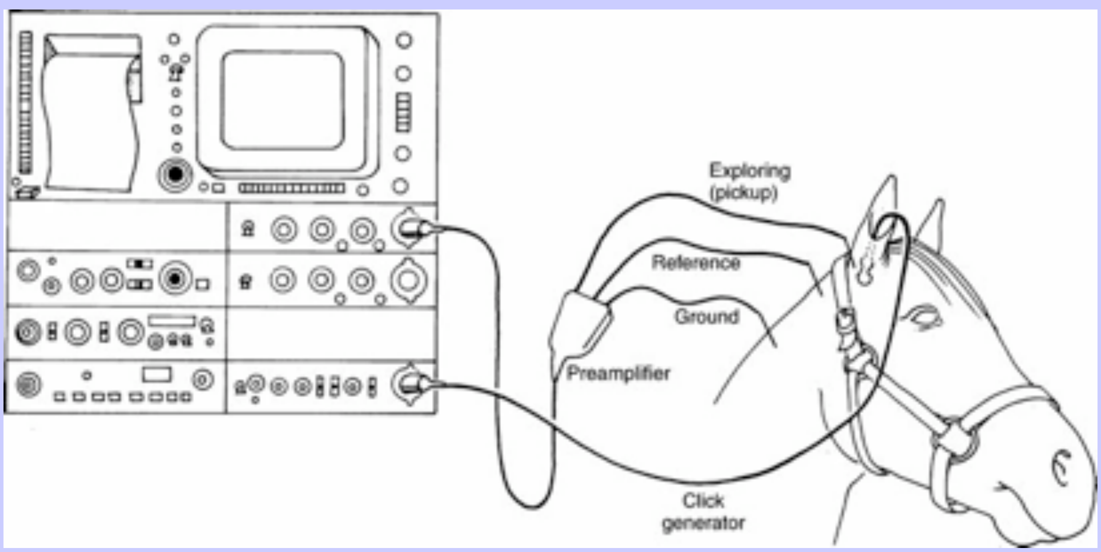
MYOPATHIES, MYOSITIS, AND MYOTONIA

Needle EMG may be helpful in evaluating horses with signs of primary muscle disease, such as muscle tremors, muscle fasciculations, muscle stiffness, weakness, and percussion dimpling. Myopathies generally are classified into inflammatory or degenerative types.[29] Degenerative myopathies are characterized by an intact motor unit, but a loss of viable muscle fibers, which results in an increased number of polyphasic MUAPs with decreased duration (see Figure 10.3-8). Inflammatory myopathies (myositis) are characterized by a subacute or acute degeneration of muscle fibers with active infiltrates of inflammatory cells. The characteristic potentials are increased insertional activity, brief low-voltage MUAPs, fibrillation potentials, and positive 554
sharp waves. Needle EMG is a valuable aid in the diagnosis and localization of focal and diffuse myopathies. 555
Primary myopathies such as exertional rhabdomyolysis and myositis can be differentiated from myotonia and myotonia-like syndromes by needle EMG examination.[21] Furthermore, fibrillation potentials and positive sharp waves have been observed on EMG examination in horses with chronic myositis, exertional rhabdomyolysis, shivers, and hyperkalemic periodic paralysis.[14,21] After completing the needle EMG examination, one may evaluate muscles with postinsertional activity further by muscle biopsy and microscopic evaluation.[21,30]

10.3.5.5 MYOTONIA

Myotonia is a disease characterized by an electrolyte conductance deficit in the skeletal muscle membrane.[3] One may observe fibrillation potentials, positive sharp waves, a train of positive sharp waves, and myotonic potentials on EMG examination in horses with myotonia congenita[21] and myotonia dystrophica.[31] Characteristic electrophysiologic findings include waxing-and-waning, high-frequency spontaneous and induced myotonic discharges (dive-bomber potentials) in many muscle groups, including the middle gluteal and semitendinosus muscles[21,31] (see Figure 10.3-10). One may use needle EMG to confirm the diagnosis of myotonia, to distinguish this condition from pseudomyotonia, and to localize areas for muscle biopsy (see Figure 10.3-8). Myotonia and myotonia-like syndromes also may present as tremors or even seizure activity. EMG along with a thorough physical and neurologic examination can help differentiate seizures from primary myopathy.

Figure 10.3-15 System used for auditory brainstem response testing in the horse. (From Rolf SL, Reed SM, Melnick W et al: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res* 48:910-914, 1987.)



10.3.6 Auditory Brainstem Response Testing

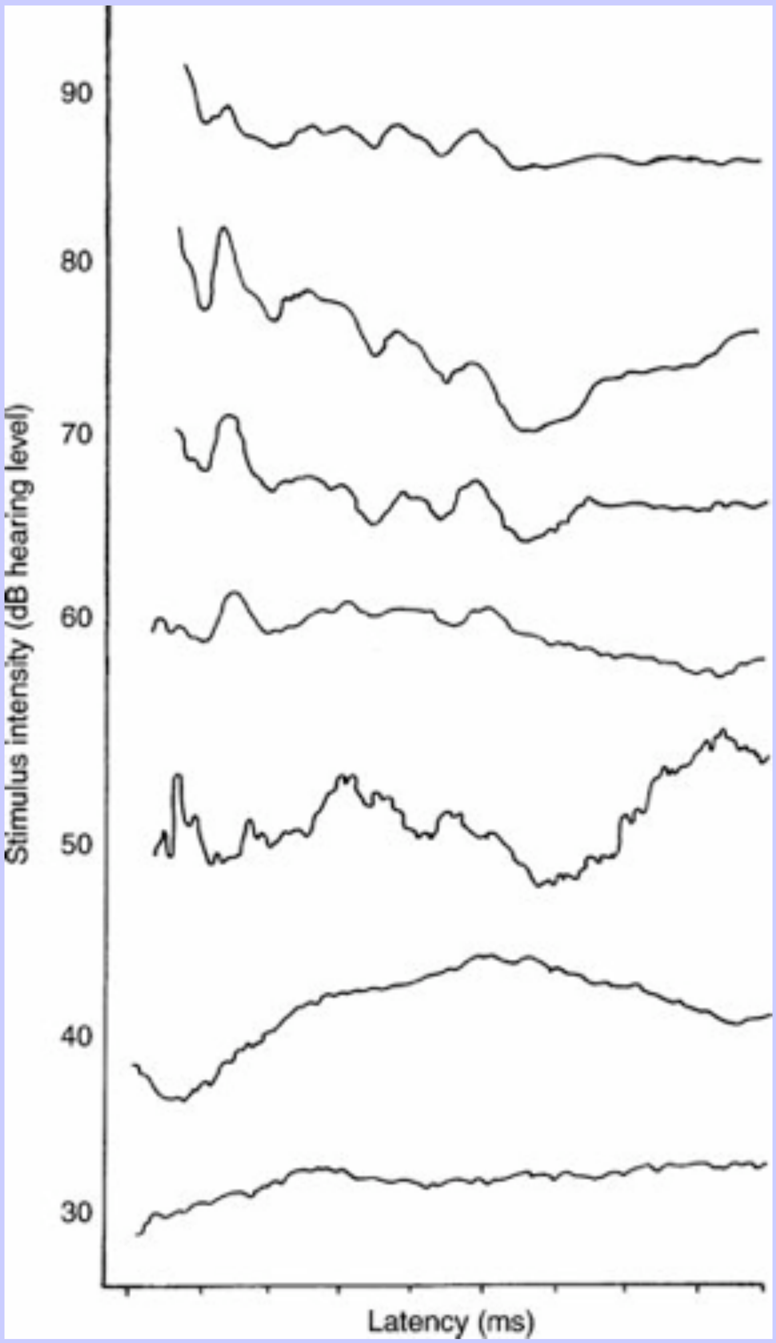
ABR testing is a method of recording potentials arising from the eighth cranial nerve and its projections in response to acoustic stimulation via surface or subcutaneously placed electrodes. The ABR is those evoked potentials, or waves, arising within the first 10 ms after delivery of an acoustic stimulus (clicks) (Figure 10.3-15). In human beings, ABR is recognized as consisting of from five to seven waves, generally designated I through VII. Of these, waves I through V are the most common. In dogs and cats fewer waves are observed.[32,33]

In human beings and animals, a correspondence exists between these waves and certain anatomic generator sites[33–39]:

1. Wave I is generated by bipolar neurons of the eighth cranial nerve.
2. Wave II also may be generated partly by the eighth cranial nerve.
3. Waves II through V probably reflect more generalized activity in the auditory system in the medulla and pons and may represent neural activity ipsilateral and contralateral to the stimulated ear.

A wide range of clinical applications of ABR in human beings has been well described.[19,34,37,39–46] However, its use in the horse has been limited.[47,48] ABR testing is a method of assessing not only auditory function but a 555
variety of neurologic disorders involving the brainstem. ABR testing is unaffected by the state of arousal of the 556
test subject and responses are not degraded by sedation or general anesthesia.[37,45]

Figure 10.3-16 Mean latency waves at 136 dB, sound pressure level (SPL) through 87 dB SPL. Five waves are present except at 40 of 80 dB SPL. (From Rolf SL, Reed SM, Melnick W et al: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res* 48:910-914, 1987.)

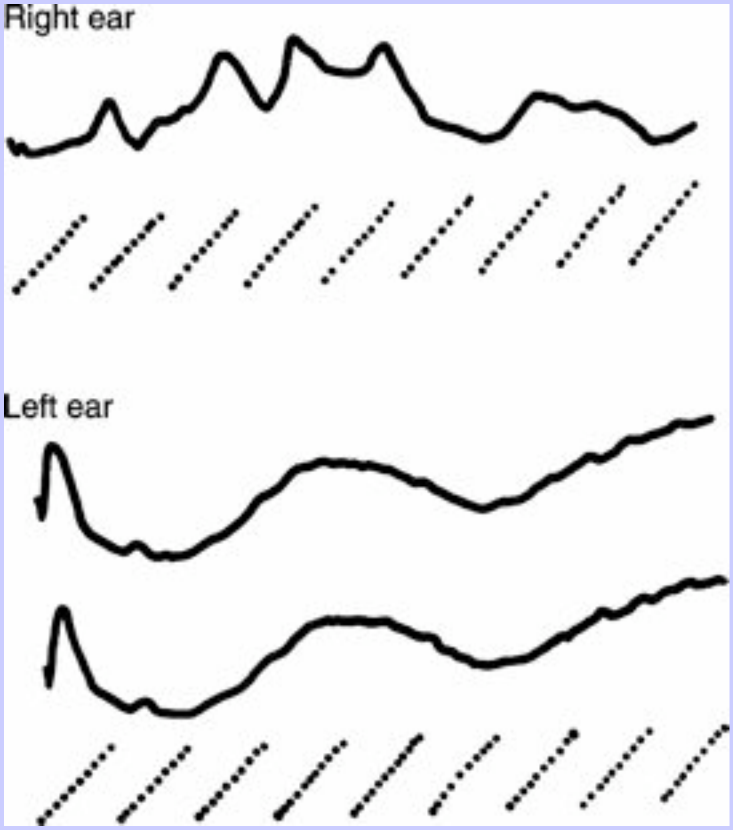


One can examine horses awake, with or without mild sedation, or anesthetized (see Electromyography). If one tests an awake horse, one stimulates each ear and records the resultant waveforms independently. If one anesthetizes the patient, one examines the uppermost ear first, turns the horse, and examines the lower ear.

One commonly observes five peaks, and these are considered analogous to waves I through V in human beings[*] (Figure 10.3-16). Mean latencies have been reported previously in horses under general anesthesia.[51] As has been observed in dogs and cats,[32,33] latencies of the waves decrease as stimulus intensity increases. One can use the ABR clinically in horses with head tilts (Figure 10.3-17) to verify the presence of hearing loss (Figure 10.3-18), middle or inner ear infections, and stylohyoid osteomyelitis. ABR testing also may be helpful in the diagnosis and prognosis of traumatic, infectious, or inflammatory brainstem lesions such as vascular infarcts or anomalies, ischemic fibrocartilaginous emboli, basisphenoid bone fracture, and protozoal encephalomyelitis. One can assess the quantitative and qualitative characteristics of the ABR-generated waveforms. Persistent prolonged latencies suggest retrocochlear or conductive abnormalities.[37] Interaural latency differences of wave V may suggest unilateral brainstem disease, except when cochlear disease is present. Qualitative ABR changes are of greater use in equine medicine because quantitative measures of normal and abnormal horses are limited. In human beings qualitative changes such as peak presence, waveform morphologic characteristics, and response 556
stability are of greater use in the diagnosis of central disorders, particularly acoustic neuromata and 557
demyelinating diseases.[37]

Figure 10.3-17 Photograph of foal with a right head tilt and dropping of the right ear. Auditory brainstem response (see Figure 10.3-18) shows a hearing loss in the left ear, the presumed cause of his head tilt. The right ear was normal.

Figure 10.3-18 Auditory brainstem response of the foal in Figure 10.3-17 showing normal right ear and abnormal left ear.



The limitations of ABR include a dependence on cochlear function; susceptibility to extraneous noise, which may affect waveform morphology; and the limits of the machinery in excluding 60-cycle interference.

10.3.7 Electroencephalography

EEG is the graphic recording of electric activity arising from the cerebral cortex. The origin of this electric activity is not known but is thought to arise from pyramidal cell dendrites located within a 2-mm depth of the cerebral cortex. This electric activity may be modified by deeper structures such as the brainstem, reticular activating system, and thalamus. EEG is an extension of the neurologic examination and is a valuable tool for determining the presence of a cerebral disease, localizing it, determining its extent (focal or diffuse), differentiating between inflammatory and degenerative changes, and establishing a prognosis.

EEG has been used and reviewed extensively in human beings[52,53] and small animals,[8,49] but little work has been done in the horse.[54] This discussion presents a brief description of the use, interpretation, and limitations of EEG so that one may gain a better understanding regarding its use.

10.3.7.1

NORMAL PATTERNS

One should evaluate the EEG for symmetry, waveform, morphology, frequency, and amplitude. The bipolar montage, as discussed previously, allows comparison of cortex to cortex. One can compare the potentials generated by the left occipital region with those of the right occipital cortex, the potentials generated by the left frontal cortex region with those of the right frontal area, and the potentials generated by the left side (left frontal–left occipital) with those of the right side (right frontal–right occipital) (Figure 10.3-19). Normal EEG potentials in the horse consist of a dominant waveform in the awake alert horse of low voltage (8 to 15 μV) and fast activity (18 to 30 Hz) (Table 10.3-2). Usually this activity is superimposed over a low to medium voltage (10 to 40 μV) and slow activity (5 to 10 Hz). Muscle artifact occasionally interrupts the baseline, when the animal shakes its head, moves its eyes, or twitches the facial muscles.

559

10.3.7.2 ABNORMAL PATTERNS

Diseases of the cerebral cortex can alter frequency, amplitude, and symmetry of EEG patterns. Low voltage–fast activity and spikes may occur with ongoing irritative processes such as seizures or inflammation (Figure 10.3-20). High voltage–slow activity indicates death of neurons in diseases such as brain abscess (Figure 10.3-21) and neoplasia. However, low voltage–fast activity and high voltage–slow activity are not pathognomonic for any disease process but suggest the various disease states previously discussed. Localized EEG changes indicate focal cortical disease such as infarcts, hemorrhage, early tumor, or abscessation (see Figure 10.3-21), whereas generalized EEG changes may indicate a diffuse cortical or subcortical disease such as infection (see Figure 10.3-20), trauma, space-occupying lesions (hydrocephalus, tumor), idiopathic epilepsy, or a systemic metabolic illness (hepatic encephalopathy). Serial recordings may be helpful in following therapy and the progress of disease. Generally, artifacts such as ocular movement and facial muscle twitches produce asymmetric and symmetric low voltage–slow activity, whereas hypothyroidism may produce

symmetric low voltage–medium-to-slow activity.[49] The difficulty in EEG in the horse is differentiating artifact (muscle movement, eye movement, head shaking, EEG artifact) from true EEG changes. For reemphasis, EEG alone is only one part of the diagnostic workup. One always should interpret the EEG examination along with the history, clinical signs, and neurologic examination.

10.4.1
Seizures

Seizures are clinical manifestations of rapid excessive electric discharges from the cerebral cortex that result in involuntary alterations of motor activity, consciousness, autonomic functions, or sensation.[1–5] Seizures may be

referred to as *fits, attacks, strokes, convulsions,* or *epilepsy*. A true seizure, however, refers to a specific clinical event regardless of cause or morphology. Epilepsy refers to reoccurring seizures with nonprogressive intracranial alterations, which may be genetic or acquired. True inherited epilepsy probably does not occur in horses.[2] Convulsions, however, refer to seizures accompanied by tonic-clonic muscle activity and loss of consciousness. Convulsions may include a generalized seizure.

Seizures in horses can be classified into three broad forms based on clinical signs: partial seizure, generalized seizure, and status epilepticus. A partial seizure involves a discrete area of the cerebral cortex and results in localized clinical signs, such as facial or limb twitching, compulsive running in a circle, or self-mutilation. One may observe a partial seizure after cervical myelography, anesthesia, and cranial trauma that may spread throughout the cerebral cortex and produce a secondary generalized seizure. A generalized seizure involves the entire cerebral cortex and results in generalized tonic-clonic muscle activity over the whole body, with loss of consciousness. Generalized seizures are the most common form of seizures observed in adult horses and foals.[2,3] Status epilepticus is characterized by generalized seizures occurring in rapid succession and is uncommon in horses.[2]

10.4.1.1 PATHOGENESIS

Adult horses have a high seizure threshold. Severe damage must occur to the brain before adult horses have seizures. Foals, however, have a lower seizure threshold and are more susceptible to conditions causing seizures.[6] Intracranial or extracranial factors may cause seizures[2] (Tables 10.4-1 and 10.4-2). The most common causes of seizures in foals under 2 weeks of age are neonatal maladjustment syndrome, trauma, and bacterial meningitis.[6] The most common causes of seizures in foals less than 1 year of age are trauma and idiopathic epilepsy in Arabian foals.[2,3] The most common causes of seizures in adult horses older than 1 year 560
of age are brain trauma, hepatoencephalopathy, and toxicity.[2] Tumors, especially pituitary adenoma, may 562
cause seizures and blindness in horses older than 7 years.[2]

TABLE 10.4-1 Known and Suspected Causes of Seizures in Horses Less Than 1 Year of Age

	DIFFERENTIAL DIAGNOSIS		
CLASSIFICATION	EXTRACRANIAL	INTRACRANIAL	DIAGNOSTIC AIDS
Anomalies (congenital)		Hydrocephalus	
		Hydranencephaly	1–6, 8
		Benign epilepsy	11

The pathophysiologic mechanisms of seizures are not known thoroughly. Current research has focused on intracellular neuronal and synaptic events that initiate excessive and prolonged neuronal depolarization, known as "paroxysmal depolarization shift." Several mechanisms are thought to cause paroxysmal depolarization shifts and seizures and include increased excitatory neural transmitters, decreased inhibitory neural transmitters (γ-aminobutyric acid, GABA), alteration in neural transmitter receptor sites, or a derangement in the internal cellular metabolism of the neuron.[7,8] The most widely held hypothesis for seizure initiation is development of excitatory postsynaptic potentials. Seizures may develop because of a summation

of synchronous excitatory postsynaptic potentials in large groups of neurons that may be precipitated by an increase in excitatory neurons, a decrease in inhibitory neurons, a decrease in inhibitory neurotransmitters, or any combination of these.[7,9] Once a "critical mass" of neurons has fired, an uncontrolled spread of electric activity may occur over the cerebral cortex and precipitate a generalized seizure. Head trauma and decreased cerebral blood supply have been implicated in creating seizure foci. Head trauma may result in cerebral cortical hypoxia, which in turn may lead to necrosis of inhibitory neurons. Because cerebral inhibitory neurons are more sensitive to hypoxia than excitatory neurons, a loss of inhibitory neurons allows the spread of these excitatory postsynaptic potentials and seizure development.[10]

Inhibitory neurons surround excitatory neuron groups and check areas of intense stimulation. Decreased inhibitory neurotransmitters in these areas, such as GABA, have been implicated in seizure formation in animals. Application of penicillin directly to the brain of laboratory animals suppresses GABA and induces seizures.[11] These seizures can be blocked by use of other agents that potentiate inhibitory neurotransmitters. Phenobarbital and pentobarbital potentiate inhibitory neural transmitters, such as GABA, and block seizure foci caused by penicillin and hypoxia.

Alterations in the neuronal cell microenvironment may lead to seizure generation. Systemic and local neuronal electrolyte abnormalities may disturb excitatory neuron homeostasis and lead to spontaneous and excessive action potentials.[7] Intracellular potassium released during neuronal activity may reach sufficient concentration to move the resting membrane potential toward the threshold and generate a seizure focus.[12] Spontaneous action potentials generated by alteration in intracellular potassium concentration may spread to other parts of the cerebral cortex, causing a generalized seizure.

Furthermore, alterations in one intracellular neuronal electrolyte may alter the homeostasis of other intracellular electrolytes. This alteration is supported by the observation of increased intracellular potassium concentration, together with decreased intracellular calcium and chloride concentrations, in the long-duration changes in excitability known to occur during interictal epileptogenesis and the transition from interictal to ictal activities.[13,14]

Alterations in sodium conductance also have been implicated in causing seizures. Rapid influxes of sodium into the neuron may lead to hyperexcitability of the neuron and rapid firing. Phenytoin, a hydantoin derivative, blocks these rapid influxes of sodium into neurons and suppresses repetitive firing by hyperexcitable neurons.[15] Thus a complex interaction may occur between these electrolytes and the internal cell homeostasis that precipitates seizure formation.

10.4.1.2 CLINICAL SIGNS AND DIAGNOSIS

Seizure activity is manifested clinically in a variety of ways depending on the area and the extent of the cerebral cortex involved. In partial seizures, asymmetric twitching of a limb, facial twitching, excessive chewing, compulsive running, or self-mutilation may occur.[2] A localized seizure may develop into a generalized seizure.

In a generalized seizure, one may observe three distinct clinical periods. Just before the seizure (aura), horses may exhibit signs of anxiety and uneasiness. During the seizure (ictus), horses may become recumbent, unconscious, and have symmetric clonic muscle contractions (contractions and relaxations of muscles occurring in rapid succession), followed by symmetric tonic muscle contractions (continuous unremitting muscle contractions).[2,3] Horses also may show deviation of eyeballs, dilated pupils, ptyalism, trismus or jaw

clamping, opisthotonos, lordosis or kyphosis, violent paddling movements of the limbs, uncontrolled urination and defecation, and excessive sweating. A generalized seizure may last from 5 to 60 seconds.[2] After the seizure (postictus), horses may show depression and blindness for hours to days.[2,3]

Diagnosis of seizure is based on history, clinical signs, and ancillary diagnostic tests to determine an underlying cause, whenever possible (see Tables 10.4-1 and 10.4-2). In all paroxysmal, involuntary neurologic events, one should consider seizures first unless the cause is proved otherwise. Careful questioning of the owner can reveal information about the event, the time of day, relationship to feeding, date, unusual environmental circumstances (stimuli such as thunderstorms, fireworks, changes in housing), recent trauma, febrile episodes, exposure to drugs or toxins, recent behavioral changes, and the seizure history of the dam,
sire, and other siblings. One must rule out other conditions that mimic seizures, including painful conditions 562
(colic, limb fractures, exertional myopathy), hyperkalemic periodic paralysis, and syncope. In these conditions 563
horses do not lose consciousness but remain bright and alert. Horses with hyperkalemic periodic paralysis may show prolapse of the nictitating membranes of the eye and muscle fasciculations but remain anxious, alert, and have normal pain perception. This condition occurs in Quarter Horse and Quarter Horse crosses 2 to 3 years of age. Serum potassium concentration in these horses ranges from 5.5 to 9.0 mEq/L during or shortly before collapse.[16,17]

One can confuse narcolepsy and cataplexy with seizures. Most narcoleptic horses (except for some ponies) remain standing with the head hanging close to the ground. If recumbency occurs, loss of muscle tone and rapid eye movement (REM) sleep may follow.[18] Cardiac arrhythmias or severe murmurs may precipitate syncopal episodes. Auscultation of the heart may help determine the presence of severe murmurs, and electrocardiography may help determine the presence of arrhythmias. Icteric mucous membranes may be apparent in horses with hepatoencephalopathy, and diarrhea may be evident in horses after toxin ingestion.

One should perform a complete neurologic examination to determine the presence of other neurologic signs. One should peform the neurologic examination during the interictal period, for an immediate postictal examination may reveal depression, weakness, blindness, and crossed extensor reflex and may lead to false anatomic localization of lesions.[1–3]

Cerebrospinal fluid from the cisterna magna may be helpful in determining the cause of seizures. Increased cerebrospinal fluid protein, red blood cell count, white blood cell count, and abnormal differential white blood cell count may be helpful in determining the cause of the seizure.[1–3] Increased cerebrospinal fluid lactic acid concentration also may be evident in horses with cerebral abscess.[19]

TABLE 10.4-3 Anticonvulsant Drugs Used to Treat Seizure Disorders in Horses

REGIMEN	DRUG	50-kg FOAL	450-kg HORSE
Initial therapy (including status epilepticus)	Diazepam	5–20 mg IV[*]	25–100 mg IV
	Pentobarbital	150–1000 mg IV	To effect
	Phenobarbital	250–1000 mg IV	2–5 g IV
	Phenytoin	50–250 mg IV or PO q4h	—
	Primidone	1–2 g PO	—
	Chloral hydrate (±MgSO, barbiturate)	3–10 g IV	15–60 g IV
	Xylazine[†]	25–100 mg IV or IM	300–1000 mg IV or IM
	Guaifenesin (±barbiturate)	To effect	40–60 g
	Carbamazine	250–500 mg	
	Triazolam	1 g	
Maintenance therapy	Phenobarbital	100–500 mg PO b.i.d.	1–5 g PO b.i.d.
	Phenytoin	50–250 mg PO b.i.d.	500–1000 mg PO t.i.d. (low therapeutic index)
	Primidone	1 g PO s.i.d. or b.i.d.	

* IV, Intravenously; IM, intramuscularly; PO, by mouth.

† Should be used only in an emergency situation until an appropriate anticonvulsant agent can be started.

Skull radiographs may help determine the presence of traumatic skull fractures. Bone scan may reveal nondisplaced skull fractures. A fundic examination may reveal papillary edema, detached retina, or active inflammation that may suggest trauma or an infectious cause. Electroencephalography and a computed tomography scan may be helpful in localizing and determining the cause of a seizure.[20–22] If one cannot find an underlying cause, then one may make a diagnosis of idiopathic epilepsy.[2,3]

10.4.1.3

TREATMENT

One must base treatment of horses having seizures on medical considerations, client considerations, owner preference and compliance, and the long-term expense of medication. One should base starting anticonvulsant therapy on the frequency and severity of the seizures of the horse. One may extrapolate guidelines for anticonvulsant therapy from treatment guidelines used in human beings and small animals. Generally, anticonvulsant therapy is indicated in status epilepticus (which occurs rarely in adult horses and uncommonly in foals): one seizure occurring every 2 months; clusters of seizures more than 3 or 4 times per year; or several multiple seizures occurring over 1 to 3 days.[23] Foals with idiopathic epilepsy that have several seizures over 1 to 3 days also may require short-term (1 to 3 months) anticonvulsant therapy.[2,3] The chronic use of

anticonvulsants in horses is rare. Table 10.4-3 lists therapy guidelines.[2–4] One should decrease maintenance therapy slowly to determine if continued therapy is needed. The goals of anticonvulsant therapy are to reduce the frequency, duration, and severity of seizures without intolerable side effects. The complete elimination of a 563
seizure may not be possible. The best initial treatment for seizures in horses is diazepam and phenobarbital 564
sodium. One must treat each horse as an individual and tailor the treatment dosages to fit the individual.

Adult horses and foals in seizure also may benefit from 1 g/kg dimethyl sulfoxide given intravenously as a 10% solution with lactated Ringer's solution or 5% dextrose. Dimethyl sulfoxide scavenges free oxygen radicals released in damaged tissue and helps maintain cerebral blood flow by reducing thromboxane production, which may result in vasoconstriction and platelet aggregation.[24]

Corticosteroids may be effective initially as an anticonvulsant therapy. One should give a single dose of 0.1 to 0.2 mg/kg dexamethasone intravenously initially and should reevaluate the horse the next day.[25] Corticosteroids may stabilize neuronal membranes and decrease seizure foci. Corticosteroids and dimethyl sulfoxide may be synergistic.

Several drugs are contraindicated in seizures, and they include acetylpromazine, xylazine, and ketamine. Although acetylpromazine has been used to control seizures in foals, the drug is risky because of its ability to lower the seizure threshold.[2,3] Xylazine decreases cerebral blood flow and increases intracranial pressure, which may exacerbate cerebral hypoxia and worsen seizures. However, giving xylazine may be necessary in an emergency situation until a more appropriate drug becomes available. Ketamine increases cerebral blood flow, oxygen consumption, and intracranial pressure and may exacerbate seizures.

10.4.2 Narcolepsy

Narcolepsy is a rare, incurable sleep disorder of the central nervous system characterized by uncontrolled episodes of loss of muscle tone (cataplexy) and sleep.[1,3,4] The disease has been reported in Suffolk and Shetland foals (the fainting disease),[26] Welsh ponies, a Miniature horse, and in the Thoroughbred, Quarter Horse, Morgan, Appaloosa, and Standardbred.[1,3,4,27] A familial occurrence is thought to exist in affected Suffolk and Shetland pony foals.[3]

10.4.2.1 PATHOPHYSIOLOGY

Four components of narcolepsy are apparent in human beings and include excessive daytime sleepiness associated with short periods of REM sleep, cataplexy, hypnagogic hallucinations, and sleep paralysis.[4,28] Cataplexy or sudden collapse with complete inhibition of skeletal muscle tone occurs in horses with narcolepsy.[1,3,4] Respiratory and cardiac muscles are spared.[1]

The normal sleep cycle consists of two stages. Slow wave sleep (non-REM sleep), mediated by serotonin, occurs first and originates from the midline raphe of the pons. Slow wave sleep is followed by fast wave (REM) sleep, which is mediated by norepinephrine. These centers are located in the locus ceruleus of the pons.[1,29] Slow and fast wave sleep act through the ascending and descending activation system of the reticular formation.[1] In fast wave sleep, when REM occurs, the locus ceruleus activates the medial reticular formation nucleus, the axons of which descend the spinal cord to inhibit the lower motor neurons of the somatic efferent system. This inhibition produces atonia.[1,30,31] Electroencephalography recordings during fast wave sleep are

characterized by low-amplitude, fast activity. Electromyographic recordings during fast wave sleep show no recordable muscle tone.[1]

With narcolepsy and cataplexy a biochemical abnormality of the brainstem or sleep-wake center may be responsible for the disease. A recent study showed that decreased concentrations or turnover of serotonin, dopamine, or norepinephrine may play a role in narcolepsy and cataplexy.[1,32] A cholinergic mechanism mediated by acetylcholine also may play a role.[33] No morphologic lesion has been found to cause sleep dysrhythmia.[3]

Cataplectic episodes usually are not associated with exercise. Petting or stroking of the head and neck, hosing with cold water after exercise, leading out of a stall, the initiation of eating or drinking, and stall rest may precipitate a cataplectic episode.[4]

The onset of narcolepsy or cataplexy occurs at approximately 6 months of age.[1] However, adult onset has been described.[4] A predictable pattern of duration and frequency of attacks is set within the first 1 to 2 weeks following the onset of disease.[1]

10.4.2.2 CLINICAL SIGNS

Clinical signs of narcolepsy vary from mild muscle weakness to complete collapse. Adult horses may drop their heads, buckle at the knees, and stumble.[1,3,4] If forced to walk, the horse may be ataxic. Pony breeds are more likely to become recumbent.[4] Horses and ponies that collapse may show absent spinal reflexes and REM sleep. Occasional sudden contraction of a limb or trunk muscle can occur resulting in a spasmodic motion. Episodes may last from a few seconds to 10 minutes.[1,3,4] The horse maintains eye and facial responses, normal cardiovascular function, and normal respiratory function during the attack. Horses can be aroused from the attack with varying degrees of difficulty, and most recover and rise quietly without incident.[3] Affected horses are neurologically normal between attacks.[1,4]

10.4.2.3 DIAGNOSIS

Diagnosis of narcolepsy is based on history, clinical signs, pharmacologic testing, and the absence of other diseases. A complete blood count and serum biochemical profile may help determine underlying systemic and metabolic abnormalities. Cerebrospinal fluid is normal in affected horses.[4] Electroencephalography and needle 564

565 electromyography during an attack may reveal fast waves of REM sleep and the absence of postinsertional activity of resting muscle.[1]

A provocative test is useful in diagnosing narcolepsy or cataplexy in horses. Physostigmine salicylate, an anticholinesterase drug, given at 0.06 to 0.08 mg/kg slowly intravenously and 0.05 to 0.1 mg/kg slowly intravenously precipitates a cataplectic attack within 3 to 10 minutes after administration in affected horses.[3,4,27] This compound crosses the blood-brain barrier.[4] Careful monitoring of the horse after physostigmine administration is necessary because of untoward effects such as colic and cholinergic stimulation.

Atropine sulfate, a muscarinic blocker, given at 0.04 to 0.08 mg/kg intravenously or 20 to 60 mg intravenously reduces the severity of cataplectic attacks minutes after administration and can prevent their reoccurrence for

12 to 30 hours following administration.[3,4] Response to atropine sulfate supports a possible cholinergic mechanism for causing cataplexy. One must monitor horses given atropine sulfate for ileus and colic.

Neostigmine, a cholinesterase inhibitor, given at 0.005 mg/kg intravenously does not cross the blood-brain barrier and therefore has no effect on cataplectic attacks. However, neostigmine may help rule out conditions causing muscle weakness such as myasthenia-like syndromes and botulism. Horses with muscle weakness show increased muscle tone and a favorable response to neostigmine.

10.4.2.4 DIFFERENTIAL DIAGNOSIS

One should consider other causes of acute collapse in the horse. Acute collapse without warning is characteristic of cardiovascular collapse or syncope. Atrial fibrillation, ruptured chordae tendineae, myocardial infarction, myocardial fibrosis, aortic endocarditis, and pericarditis have been associated with syncope in horses. Cerebral hypoxia may occur in these conditions and may lead to coma, with or without signs of cardiac failure. One should consider seizures in ruling out acute collapse and also should consider botulism (shaker foal syndrome, forage poisoning), myasthenia-like syndrome, postanesthetic neuromyopathy, exertional rhabdomyolysis, and metabolic causes such as hyperthermia, shock, hypoglycemia, hypocalcemia, hypo- or hyperkalemia, endotoxemia, anaphylaxis, and snakebite. Horses with hyperkalemic periodic paralysis also may have attacks similar to those in horses with narcolepsy. These horses typically have muscle tremors and may become recumbent with hyporeflexia but are alert and anxious. Attacks in horses with hyperkalemic periodic paralysis may last up to 15 minutes, and the horse usually stands without incident. Diagnosis of this condition is based on clinical signs, serum potassium concentration, potassium chloride provocation, and electromyographic findings.[16,17]

Tight whole-body restraint may induce a cataplectic state in neonatal foals. This response is thought to be an inherent in utero mechanism that prevents violent movements, especially during parturition.

10.4.2.5 TREATMENT AND PROGNOSIS

Imipramine, a tricyclic antidepressant drug, is used to control narcolepsy and cataplexy.[1,3,4] The drug blocks the uptake of serotonin and norepinephrine and decreases REM sleep.[4] One can use imipramine at a dose of 0.55 mg/kg intravenously or 250 to 750 mg orally.[3,4] Oral administration produces inconsistent results.[4] As mentioned previously, atropine sulfate can provide relief from acute attacks for up to 30 hours, but one must weigh its use against the adverse gastrointestinal side effects it causes.

The prognosis for narcolepsy or cataplexy varies. Some newborn Thoroughbreds and Miniature horses may have severe attacks but recover fully.[3] In Shetland and Suffolk ponies the disease may persist throughout life, as is true with the adult-onset form.[1,3,4] In horses 1 to 3 years of age, several episodes may occur but are without permanent consequence.[3]

10.5—Spinal Cord, Vertebral, and Intracranial Trauma

Hilary K. Matthews

Yvette S. Nout

565

566

10.5.1

Spinal Cord and Vertebral Trauma

Trauma to the central nervous system (CNS) is the most common cause of neurologic disease in horses, accounting for 22% of CNS disorders in one study. In the same study, 50% of horses with traumatic CNS disorders were diagnosed with cervical spinal cord disease. Trauma to the vertebral column frequently results in severe spinal cord damage and therefore should be considered in any acute case of neurologic disease. Commonly, trauma occurs because of falling or colliding with a large stationary object such as a jump, fence, or another horse and may be caused by a penetrating injury. Trauma to the cervical vertebral column often results from a fall on the flexed neck. Neurologic signs usually appear immediately after the accident but may occur weeks to months after the initial insult because of delayed damage to the spinal cord caused by instability, arthritis, or bony callus formation. Clinical signs in traumatic injuries reflect the neuroanatomic location and range from inapparent to severe incapacitating tetraparesis or tetraplegia. One study showed that lesions causing

recumbency mostly were found in the caudal cervical or thoracic spinal cord, whereas lesions of nonrecumbent horses mostly were found farther cranial in the cervical spinal cord.[1]

An age-related distribution in the location of trauma has been noted. Foals and young horses are more susceptible to vertebral trauma than adult horses, especially in the cranial cervical and caudal thoracic areas. An increased incidence of luxations, subluxations, and epiphyseal separations occurs in young horses and may be because cervical vertebral growth plate closure does not occur until 4 to 5 years of age. Adult horses are more prone to caudal cervical (C5 to C7) and caudal thoracic injuries, and considerable force is required for injury.[2] Table 10.5-1 lists the location, type of trauma, inciting incident, and clinical signs associated with the common types of vertebral trauma.

10.5.1.1 PATHOPHYSIOLOGY

Spinal cord damage following trauma is a dynamic process, and the severity is related to the velocity, degree, and duration of the compression or traction forces. The development of spinal cord damage does not coincide 566
with the clinical picture, because pathologic changes may progress in severity for approximately 1 week, even 567
in the face of clinical improvement.[3] Neurologic deficits following spinal cord injury occur through *primary* and *secondary* mechanisms of injury. The primary injury results from the immediate mechanical disruption of neural pathways, whereas secondary spinal cord injury occurs through alterations in the metabolic environment within injured spinal cord tissue in part from release of endogenous pathophysiologic factors. Mechanisms particularly involved in the secondary spinal cord injury are not understood fully; however, the disruption of cellular and subcellular membranes of glia, neurons, and vascular endothelial cells is believed to be the initiator of this autodestructive cascade of events.[4] Classically, initial spinal cord trauma results in changes in the center, or gray matter, of the cord. The reason for this is not entirely clear but is most likely related to the rich blood supply and increased metabolic requirements for oxygen and glucose of the nerve cell bodies in the gray matter. However, the edema, hemorrhage, and hypoperfusion of the gray matter progress outward and lead to central necrosis, white matter edema, and demyelination of the entire spinal cord.[3]

TABLE 10.5-1 Common Types of Vertebral Trauma

LEVEL OF INJURY	AGE	TYPE OF VERTEBRAL TRAUMA	COMMON TRAUMATIC INCIDENT	SYNDROME
Cervical	Foal to yearling	Fracture of dens, luxation C1-C2	Hyperflexion (e.g., somersault)	Tetraparesis, respiratory depression, death
Cervical	Young adult	Epiphyseal fracture	Hyperextension	Tetraparesis to tetraplegia
Cervical	Adult	Compression fracture	Head-on collision	Tetraparesis to tetraplegia
Cranial thoracic	Usually young	Fracture of dorsal spinous process	Flipping over backward	Often none
T2-S1	Any	Transverse fracture of vertebral arch, with dislocation	Somersaulting or falls	Paraparesis
Sacroiliac subluxation	Adult	Subluxation	Falls or slipping on ice	None
Sacral fracture	Any	Compression	Fall over backward or dog-sitting when backed	Urinary and fecal incontinence with or without posterior paresis; paralysis of the tail and anus

From Reed SM: Spinal cord trauma. In Robinson NE, editor: Current therapy in equine medicine, ed 2, Philadelphia, 1987, WB Saunders.

Early, often progressive hemorrhage is one of the hallmarks in acute spinal cord injury. Loss of microcirculation predominantly involving capillaries and venules spreads over considerable distance cranial and caudal to the site of injury.[5] Within minutes the spinal cord swells at the injury site, and ischemia occurs when cord swelling exceeds venous blood pressure. Multiple mechanisms likely are involved in secondary spinal cord injury, including vascular, inflammatory, biochemical, and molecular events.[4–6] Currently, one proposal is that the development of spinal cord ischemia is the most important cause of secondary spinal cord injury.[4,6]

Spinal cord ischemia develops over several hours. In other species a brief period of systemic hypertension followed by systemic hypotension has been demonstrated to occur immediately after initial spinal cord injury. The systemic hypotension can last for several hours and is referred to as spinal shock.[4,6] Furthermore, following injury, the spinal cord is incapable of maintaining constant blood flow independent of systemic blood pressure. This loss of autoregulation results in progressive spinal cord hypoperfusion through destruction of microvasculature, thrombus formation, vasospasm, and release of vasoactive chemicals.[6] Venous outflow obstruction in the spinal cord also occurs, leading to cavitation in the central gray matter.[3]

This ischemic hypoxic state is responsible for altered cell metabolism resulting in decreased aerobic metabolism and a shift to anaerobic metabolism, which is a less efficient method of energy production. Anaerobic metabolism results in lactic acid accumulation, causing acidosis in nervous tissue and thus decreasing glucose and oxygen consumption.[7,8] Lactic acid stimulates prostaglandin production, adenosine diphosphate release, platelet aggregation, thromboxane A_2 release, vasospasm, vasoconstriction, and the inhibition of neurotransmitter release.[7] Moreover, in hypoxic states, the Na^+,K^+-ATPase–dependent cell pump is inhibited or damaged, resulting in the inability of the cell to maintain its electric polarity.[7,8] Damage to the Na^+,K^+-ATPase (adenosine triphosphatase) pump allows for accumulation of potassium extracellularly and 567
sodium intracellularly. This mechanism is important in the development of edema.[7] 568

The sequence of biochemical events that occurs following primary spinal cord injury is complex, but a number of changes are well defined. First, extracellular concentrations of the excitatory amino acids glutamate and aspartate increase after acute spinal cord injury through the release of these amino acids from damaged neurons, the decreased uptake by ischemic astrocytes, and through depolarization-induced release.[6] The interaction of these excitotoxins with *N*-methyl-d-aspartate (NMDA) and non-NMDA receptors results in an increased intracellular sodium and calcium concentration. Intracellular calcium concentrations also increase through direct membrane damage and opening of calcium channels.[6] Particularly, the increase in intracellular calcium leads to impaired cell functioning and ultimately may result in cell death.[4,6] Impairment of cell metabolism occurs through binding of phosphates and subsequent depletion of energy, decreased mitochondrial function, vasospasm, and activation of phospholipase A_2 and other proteases. Excitotoxicity has been shown to affect neurons and oligodendrocytes. The oligodendrocyte injury occurs through effects on the glutamate α-amino-hydroxy-5-methyl-4-isoxazole propionic acid receptors and results in axon demyelination.[4] Free radical–induced lipid peroxidation of neuronal and glial cell membranes is a third important contributor to the secondary spinal cord injury.[4,6] Furthermore, lipid peroxidation of endothelial cell membranes results in platelet aggregation and propagation of spinal cord ischemia. The production of free radicals increases through the increased calcium concentrations, ischemia-reperfusion, and the presence of iron and copper complexes in areas of hemorrhage.[6]

The release of endogenous opioids resulting from trauma, especially dynorphin and other κ-receptor opioids, contributes to secondary injury by decreasing blood flow in the microcirculation.[9] However, κ-opioid agonists and antagonsists have been shown to improve outcome of acute spinal cord injury in rats.[6] The mechanism of these effects is not clear.

Currently much research is being performed on the role of apoptosis, or programmed cell death, in secondary spinal cord injury.[4,10] This form of active cell death has been shown to occur in neurons and oligodendrocytes, and protective treatment strategies are being investigated.

Controversy exists surrounding the role of inflammatory cells in acute spinal cord injury. First, the inflammatory response to CNS damage lags behind the development of secondary tissue damage, and the inflammatory response results in the development of cytotoxic and protective agents. The infiltration of inflammatory cells into damaged spinal cord tissue coincides with demyelination of surviving axons and chronic neuronal death. Inhibiting the infiltration of mononuclear cells has appeared beneficial, and a delayed pathologic effect of macrophages has been proposed to occur that is mediated through their production of quinolinic acid, which is a NMDA agonist.[6] Furthermore, the microglial cells can release cytotoxins such as

hydrogen peroxide, nitric oxide, proteinases, and cytokines such as interleukin-1 and tumor necrosis factor α within minutes of injury. However, their role in secondary spinal cord injury remains unclear.

10.5.1.2 NEUROLOGIC EVALUATION

One can localize observed clinical signs neuroanatomically to the affected area. Damage is worse in the large myelinated motor and proprioceptive fibers compared with the smaller or nonmyelinated nociceptive fibers. Therefore ataxia and loss of proprioception and motor function occurs before the loss of deep pain.[2]

One should direct initial evaluation of the patient toward stabilization and correction of any life-threatening problems such as airway obstruction, hemorrhage, cardiovascular collapse, pneumothorax, and open head injury. In addition, one must identify major long-bone fractures, because these may be the limiting factor for survival of the horse. One then should perform a systematic neurologic evaluation, as described in Chapter 10.1, to localize the site of injury.[11–13] In recumbent horses the use of a sling to assist standing may be a valuable diagnostic tool for localizing the site of injury and for assessing progression of disease and prognosis. Figure 10.5-1 shows the steps in evaluating and neuroanatomically localizing the lesion in the nervous system in a recumbent horse.[11]

Spinal shock (areflexia caudal to the lesion) and Schiff-Sherrington syndrome (extensor hypertonus in otherwise normal thoracic limbs with a cranial thoracic lesion) are infrequent and short-lived findings in the horse.[12,13] Both carry a grave prognosis.

Ancillary diagnostic aids that may be beneficial include radiography, myelography, scintigraphy, cerebrospinal fluid (CSF) analysis, nerve conduction velocities, electromyography, and computed tomography (CT).[14–16] Radiography may demonstrate fractures, luxations, subluxations, and vertebral compression. Myelography may be required to confirm cervical vertebral spinal cord compression.[16] Scintigraphy is helpful in diagnosing nondisplaced or occult fractures and soft tissue lesions.[17] Common CSF findings following spinal cord trauma include xanthochromia and mild to moderate increased total protein concentrations.[2,13] CSF analysis may be normal, especially in acute or chronic cases.[13] The use of nerve conduction velocity and electromyography testing thoroughly evaluates the lower motor neuron and aids in lesion localization. However, changes in the electromyography may not develop until 4 to 5 days following nerve damage.[18] 568

569 Currently, in human beings, CT or plain radiographs are the diagnostic aids of choice to evaluate skeletal injury, and magnetic resonance imaging is the diagnostic aid of choice to evaluate soft tissue structures such as the spinal cord and ligaments.[15] The use of CT in equine practice is increasing and appears helpful in identifying the nature and extent of spinal cord lesions.

Figure 10.5-1 Flow chart for localizing a lesion in the nervous system in a recumbent horse.

10.5.1.3

TREATMENT AND PROGNOSIS

Treatment to reverse primary spinal cord injury does not exist currently, but unless the spinal cord is severed, damage caused by stretch or laceration generally is minimal compared with the secondary damage that occurs thereafter. Treatment therefore aims at reducing the secondary tissue injury. The period of secondary injury 569
can be divided into three therapeutic windows.[6] The first 48 hours after acute spinal cord injury are dominated 570
by the vascular and biochemical changes that occur within the spinal cord. The second period results from the effects of inflammatory cells that occurs within hours of injury and peaks around 4 days after injury. The third period occurs 1 week after injury and is characterized by axonal regeneration and lesion repair. The goals of treatment are to stop the cascade of cellular events initiated by the traumatic insult: specifically, improvement in spinal cord blood flow; reduction in hemorrhage, edema, and membrane lipid peroxidation; and preservation of neural tissue.

Acute spinal cord injury often results in impaired cardiopulmonary function such as impaired ventilation, bradycardia, and hypotension.[19] Systemic hypotension may exacerbate spinal cord hypoperfusion and ischemia, and maintaining systemic blood pressure has been shown to improve spinal cord perfusion. However, hypertension has not been shown to increase spinal cord blood flow and may increase hemorrhage and edema formation.[6] Volume resuscitation clearly is indicated in shock and for restitution of tissue perfusion. The current recommendations are to maintain normotension. This point is important to consider during stabilization of the acutely injured horse but is particularly important when horses are placed under general anesthesia for the various diagnostic procedures.

Corticosteroids, alone or combined with other drugs, are the classic drugs of choice for acute spinal cord trauma. Reported dosages of dexamethasone for horses range from 0.1 to 0.25 mg/kg administered intravenously every 6 to 24 hours for 24 to 48 hours.[2,13] One should expect a favorable response within 4 to 8 hours after corticosteroid administration.[2] However, dexamethasone has not been proved to be efficacious and even may be detrimental in the treatment of spinal cord injuries.[6] One should monitor horses given corticosteroid therapy closely for the development of laminitis or *Aspergillus* pneumonia. If one observes improvement in clinical signs, one may place the horse on oral prednisolone therapy (0.5 to 1.0 mg/kg tapered over 3 to 5 days) to decrease the chance of laminitis.

The neuroprotective effect of corticosteroid is thought primarily to be mediated by free radical scavenging.[6] Furthermore, corticosteroid therapy–related effects have been attributed to a decrease in catecholamines or to a direct effect on the glutamic acid concentrations. Recently, dexamethasone, similar to methylprednisolone, has been shown to decrease apoptosis-related cell death in rats that were subjected to traumatic spinal cord injury.[20] Other potential beneficial effects of corticosteroid include reduction in the spread of morphologic damage, prevention of the loss of axonal conduction and reflex activity, preservation of vascular membrane integrity, and stabilization of white matter neuronal cell membranes in the presence of central hemorrhagic lesions. Furthermore, the antiinflammatory properties of corticosteroids may be useful in reducing edema and fibrin deposition and in reversing sodium and potassium imbalance caused by edema and necrosis. Another beneficial effect of corticosteroid is maintenance of normal blood glucose concentrations while maintaining electrolyte balance.[7]

In 1984 the first National Acute Spinal Cord Injury Study (NASCIS I) results demonstrated no significant difference between the effects of methylprednisolone sodium succinate (MPSS) and methylprednisolone on

outcomes of acute spinal cord injury patients.[21] However, results from the NASCIS II trial were more encouraging.[22,23] MPSS is a synthetic glucocorticoid with 4 times more antiinflammatory activity and 0.8 times less mineralocorticoid action compared with cortisol. MPSS is 40% to 60% bound to plasma proteins and has 2.4-hour and 12- to 36-hour plasma and biologic half-lives, respectively.[24] Beneficial effects of MPSS on neural tissue include inhibition of lipid peroxidation, eicosanoid formation, and lipid hydrolysis, including arachidonic acid release, maintenance of tissue blood flow and aerobic energy metabolism, improved elimination of intracellular calcium accumulation, reduced neurofilament degradation, and improved neuronal excitability and synaptic transmission. MPSS was selected for these trials rather than dexamethasone because the succinate radical has been shown to cross cell membranes more rapidly than other radicals.[23]

The results of this multicenter randomized, double-blind, placebo-controlled study in human beings compared the effects of MPSS, naloxone, and a placebo on the neurologic outcome of acute spinal cord injury patients.[22,23] MPSS was administered as a 30-mg/kg bolus followed by infusion at 5.4 mg/kg/hr for 23 hours. Naloxone was administered as a 5.4-mg/kg bolus followed by infusion at 4 mg/kg/hr for 23 hours. The patients' recovery was followed for 1 year. At 6 months, patients receiving MPSS within 8 hours of injury had significant improvement in motor function, sensation, and touch compared with the other groups.[22] This finding was true for patients with complete and incomplete lesions. At 1 year the MPSS group had significant improvement in motor function compared with the other groups.[23] Complications, such as wound infection and gastrointestinal bleeding, were not statistically different among the treatment groups. Mortality was approximately 6% among all groups.[22,23]

Apparently, the cell membrane antilipid peroxidation effect of MPSS is most beneficial. The dose of MPSS
used exceeds that necessary for activation of steroid receptors, suggesting that MPSS acts through 570
mechanisms unrelated to steroid receptors. Based on this study, the investigators concluded that high-dose 571
MPSS treatment within 8 hours of spinal cord injury improved neurologic recovery. The use of naloxone in spinal cord injury was not recommended.[22,23]

In a fifth trial of MPSS (NASCIS III), using essentially the same protocol for drug administration and neurologic assessment as NASCIS II, no significant benefit was found when the NASCIS II regimen of 24-hour therapy was extended to 48 hours.[25,26] Therefore the current recommendation for use of MPSS in acute spinal cord injury remains unchanged from the original recommendation of NASCIS II.[27] However, some reports dispute the usefulness of corticosteroids for treating acute spinal cord trauma and recommend further trials with MPSS.[28] The usefulness of high-dose MPSS treatment for spinal cord trauma in the horse remains to be investigated. Although more research should be performed, especially on the mechanism of action and optimal time of administration, MPSS seems to be a promising drug for treating spinal cord injury.

Because of the adverse effects of corticosteroid use and because the neuroprotective effects of methylprednisolone are independent of its glucocorticoid receptor actions, a group of steroid analogs was developed. These lazaroids, or 21-aminosteroids, lack glucocorticoid or mineralocorticoid activity and are potent antioxidants.[26,29] The 21-aminosteroid tirilazad mesylate is a potent inhibitor of iron-dependent lipid peroxidation and has been shown to be beneficial in cats and rats.[6] However, at the present time the clinical evidence is insufficient to recommend routine use of this drug, and further studies are required to show significant efficacy.[6,29] Currently the pyrrolopyrimidines are being investigated, which are antioxidants that have improved penetration of the blood-brain barrier.[29]

Dimethyl sulfoxide (DMSO) administered at 1 g/kg intravenously as a 10% to 20% solution for 3 consecutive days followed by three treatments every other day has been found to be of benefit in acute spinal cord trauma.[2,13] The pharmacokinetics of DMSO in horses indicates that twice-daily dosing is necessary to maintain adequate blood levels.[30] Reported benefits of DMSO include increased brain and spinal cord blood flow, decreased brain and spinal cord edema, increased vasodilating prostaglandin E_1, decreased platelet aggregation, decreased prostaglandins E_2 and F_2, protection of cell membranes, and trapping of hydroxyl radicals.[7,31] The exact mechanism of DMSO remains unknown. This treatment remains controversial because some researchers have found no positive effects on neurologic outcome from the use of DMSO.[32]

Although the free radical scavengers vitamin E and selenium have been shown to be beneficial in spinal cord injury, these antioxidants do not appear useful in acute spinal cord injury because of the length of time required to achieve therapeutic concentrations in the CNS.[6]

Osmotic diuretics such as 20% mannitol administered at 2 g/kg intravenously, dextran, and glycerol may be helpful in reducing brain edema. Currently, these diuretics have not been proved to be effective in spinal cord injury. One should not use these drugs continuously because their hypertonic nature may create dehydration, urine retention, and hypotension. One must maintain adequate patient hydration when using osmotic agents. Although some investigators and clinicians have found these agents to be helpful, others have found them to be of little benefit in spinal cord trauma.[7,13]

To counteract endorphin-mediated hypotension, the use of naloxone, a nonspecific opioid antagonist, in acute spinal cord injury was investigated. However, naloxone is more expensive and less effective than MPSS, and in light of the NASCIS II study, the use of naloxone is no longer advocated.[22,23] Currently, κ-opioid agonists and antagonists are being investigated because both may have beneficial effects in spinal cord injury.[6] Thyrotropin-releasing hormone (TRH) has been shown to improve functional outcome after experimental spinal cord injury, even when the administration was delayed. In one study, TRH at 2 mg/kg followed by 2 mg/kg/hr for 4 hours significantly improved the neurologic outcome in experimental spinal cord trauma in cats.[33] The beneficial results of TRH are thought to result from the neurotrophic effects of TRH and the effects of TRH on plasticity and facilitation of motor nerve firing. The effects of TRH have been reported to be better than those of naloxone or MPSS.[34]

Promising results have been obtained from research investigating the effects of calcium channel antagonists in spinal cord injury. Beneficial effects were seen with the use of nimodipine, nifedipine, diltiazem, and flunazirine but not with the use of verapamil.[6,33] One needs to administer calcium channel blockers with vasopressors to maintain systemic blood pressure. Although this class of drugs may be beneficial for treating spinal cord injury, clinical trials have not been performed and the clinical efficacy of calcium channel blockers still remains unclear. Other therapeutic strategies being investigated include CSF drainage, hypothermia,[6] the use of nerve growth stimulatory factors in the repair of the injured spinal cord in animal models.[35]

The use of nonsteroidal antiinflammatory drugs such as flunixin meglumine and phenylbutazone may decrease the inflammation associated with a traumatic episode. These compounds work by inhibiting cyclooxygenase, which converts arachidonic acid to inflammatory mediators (endoperoxides). They probably do not alter the course of the neurologic disease.

571

Antibiotics are not always necessary for treating vertebral or spinal cord trauma.[2,13] However, they are indicated in treating open fractures and secondary complications associated with a recumbent horse, such as pneumonia and decubital sores. One should base antibiotic choice on culture and sensitivity testing. Good empirical choices for broad-spectrum coverage include trimethoprim-sulfamethoxazole at 30 mg/kg orally or intravenously every 12 hours or penicillin at 22,000 IU/kg intramuscularly every 12 hours or intravenously every 6 hours in combination with gentamicin at 6.6 mg/kg intramuscularly or intravenously every 24 hours. One should undertake appropriate monitoring for aminoglycoside toxicity with their use.

Nutritional support also plays a role in the outcome following neurologic injury. In human beings, neurologic recovery from head injury has been found to occur faster in patients receiving early adequate nutritional support.[36] If the horse is able to eat and the gastrointestinal tract is functioning normally, water and good-quality hay should be available at all times. One should feed small amounts of grain 3 to 4 times a day to boost caloric intake, and one should base the amount of grain fed on the condition of the horse and its ability to tolerate grain feeding. Horses with a poor appetite or those unable to swallow may have to be tube-fed using a gruel of alfalfa and complete feed pellets. One soaks the pellets in water, usually for 8 to 12 hours, until they have a soupy consistency and then pumps them into the stomach of the horse via a nasogastric tube. The horse requires approximately 1 gal of gruel fed 3 to 4 times per day. Horses that cannot tolerate this procedure, severely depressed or comatose horses, and horses not maintainable with other feeding methods are candidates for total parenteral nutrition.

Physical therapy is important in the rehabilitative process in spine-injured horses. Controlled exercise allows the unaffected parts of the nervous system to compensate for the affected parts by increasing strength and conscious proprioception. Exercise is especially helpful in improving weakness, ataxia, spasticity, and hypermetria. In recumbent horses, massage, therapeutic ultrasound, and hydrotherapy of affected muscle groups for 10 to 15 minutes at least twice a day is important. These measures help combat necrosis and muscle atrophy of the dependent muscle groups of the horse. Passive flexion and extension of all limbs is helpful in maintaining full range of motion in recumbent horses.[37]

Surgical intervention is warranted for stabilization, fracture repair, or evidence of a compressive lesion but is not routine practice. Chapter 10.8 describes ventral stabilization surgery for horses with cervical vertebral stenotic myelopathy. One always should institute medical treatment to stabilize the patient before performing surgery.

Prognosis is based on response to therapy and is related directly to the time from injury to the institution of treatment. Horses that show rapid neurologic improvement have a fair to good prognosis. Recumbent horses or horses suffering from fractures or luxations have a guarded to poor prognosis. Horses that have lost deep pain sensation have a functional or anatomic spinal cord transection and have a grave prognosis.[13] The longer the time from loss of deep pain to treatment, the poorer the prognosis. Partial or complete recovery of horses with spinal cord trauma may take weeks to months, so time and nursing care are required.

10.5.2 Intracranial Trauma

Head trauma in horses occurs less frequently than spinal cord trauma. In one study, 5 horses out of 22 (23%) that had traumatic neurologic disease were diagnosed with intracranial trauma.[1] Head trauma in horses, which may or may not be associated with a fracture, is caused by many of the same incidents that cause spinal cord trauma. In addition, penetrating wounds, kicks to the head, and rearing up and falling over backward, often resulting in

fractures of the basisphenoid and basioccipital bones,[38] may result in intracranial trauma. Other common fractures observed in association with head injuries include mandibular, maxillary, orbital, periorbital rim, and incisive bone fractures.[1,39,40] Clinical signs resulting from trauma reflect the extent and location of the injury.

10.5.2.1 PATHOPHYSIOLOGY

Following a traumatic insult to the brain, a cycle of events occurs that is similar to spinal cord trauma. The primary events occur at the time of injury and are primarily mechanical damage, including neuronal fiber and cell membrane disruption. Similar to what has been described for spinal cord injury, the secondary injury is characterized by free radical formation, excitatory neurotoxin release, endogenous opiate release, free fatty acid release, loss of high-energy phosphates, apoptosis, CNS acidosis, and CNS ion imbalance.[41–43] Other important secondary events in traumatic brain injury (TBI) include the development of an elevated intracranial pressure (ICP), brain edema, hypoxia, and seizures. The degree of these events depends on the type and extent of the initial injury.

The types of cranial trauma from least to most severe are concussion, contusion, laceration, and hemorrhage. Concussion is a short-term loss of consciousness and is caused primarily by a direct blow to the head. Concussion is reversible and occurs without an anatomic lesion.[39,40] Contusion is associated with the immediate primary mechanical injury and results from vascular and nervous tissue damage. Although 572
contusion occurs without major structural tissue disruption, it may or may not be reparable. Contusions may 573
be on the same or opposite side of the injury and result from blows or sudden accelerations or decelerations of the head. Contusion may result in intraparenchymal hemorrhage with later cavitation.[39] Cerebral hemorrhage and laceration result from penetrating wounds (gunshots) and fractures in addition to the previously mentioned injuries. Cerebral hemorrhage in horses may be epidural, subdural (rare), intracerebral, or subarachnoid (common). Hematoma formation is of special concern because of the potential for devastating expansion within the rigid calvaria, as can occur with edema.[13,39] These processes displace brain tissue, and herniation, pressure necrosis, and brainstem compression are possible sequelae.[13,39,40]

Blood flow to the brain is controlled by changes in diameter of resistance blood vessels. The cerebral blood flow (CBF) is controlled by autoregulation whereby the CBF is maintained within a pressure range of 60 to 160 mm Hg. Beyond these limits, CBF decreases at pressures below the lower limit and increases at pressures above the higher limit. Following TBI, an elevation of the ICP generally occurs as a consequence of hemorrhage and the development of edema. The increased ICP leads to a decreased CBF caused by collapse of dural veins and subsequently to a further rise in ICP.A reduced CBF results in areas of ischemia and subsequent restriction of the delivery of substrates to the brain such as oxygen and glucose. A reduced CBF has been associated with an unfavorable neurologic outcome in human beings and has been implicated in increasing the susceptibility of the brain to secondary injury.[41]

Loss of mitochondrial function and subsequent energy depletion leads to a loss in maintenance of membrane potentials resulting in depolarization of neurons and glia. As has been described for spinal cord injury, these events lead to an increase in intracellular calcium, the release of excitotoxins, and apoptosis.[43,44] Cytotoxic edema develops through the failure of the Na^+,K^+-ATPase pump in the presence of hypoxia and the subsequent influx of water that passively follows Na^+ and Cl^-.[41,45] Cytotoxic edema develops from swelling of the cellular elements of the brain (neurons, glia, and endothelial cells). This type of edema occurs in gray and white matter and decreases the extracellular fluid volume. If capillary endothelial cells are edematous, the capillary lumen size diminishes, creating an increased resistance to arterial flow. Capillary permeability

usually is not affected in cytotoxic edema. Major decreases in cerebral function occur with cytotoxic edema, with stupor and coma being common signs.[45]

Following TBI, disruption of the blood-brain barrier, including endothelial damage, degeneration of pericytes, and loss of astrocytes, is a common finding and results in extravasation of blood components and water, which is referred to as vasogenic edema.[41,45] This type of edema is the most common found after head trauma.[39] Cerebral white matter is especially vulnerable to vasogenic edema, possibly because of its low capillary density and blood flow. This type of edema also results in increased extracellular fluid accumulation. The edema fluid is a plasma filtrate high in plasma proteins. Vasogenic edema displaces cerebral tissue and increases intracranial pressure, which may result in brain herniation. The elevated intracranial pressure further decreases (CBF).[41,45] Many of the mechanisms decreasing blood flow in spinal cord trauma also apply to cerebral trauma. Blood flow interruption is responsible for disruption in ion homeostasis (especially calcium, sodium, and potassium), and a switch to anaerobic glycolysis resulting in lactic acid production and acidosis.[40,43,46] Cell membrane lipid peroxidation with subsequent prostaglandin and thromboxane synthesis, formation of reactive oxygen species, nitric oxide, and energy failure also ensue.[43,46] Because of the high metabolic rate and oxygen demand of the brain, disruption of blood flow and normal energy-supplying processes leads to impaired nerve cell function and even cell death.[40]

10.5.2.2 NEUROLOGIC EVALUATION

Clinical signs associated with head trauma range from inapparent to recumbency with profound depression, dementia, and tetraparesis. As with spinal cord trauma, one should attend to life-threatening injuries first and then perform a complete neurologic examination. Serial neurologic examinations are vital to ensure proper treatment and to predict prognosis. One should perform reflex and nociceptive testing to rule in or out a concurrent spinal cord injury. As with spinal cord trauma, one must identify concurrent long-bone fractures, which may limit the outcome. Table 10.5-2 provides an outline for localizing the level of brain injury based on the neurologic findings.[39]

Some horses may be intractable following a traumatic incident, and sedation may be necessary for examination. One should remember that xylazine and detomidine transiently cause hypertension, which may potentiate intracranial hemorrhage.[13,39] However, xylazine has been found to cause a minor decrease in cerebrospinal pressure in normal, conscious horses.[47] Although no studies were performed on horses with cerebral trauma, xylazine is believed to be a safe sedative to use in horses with head trauma.

Severe brainstem injuries can be associated with apneustic or erratic breathing and reflect a poor prognosis.[39,40] Bilaterally dilated and unresponsive pupils indicate an irreversible brainstem lesion. One should monitor horses with bilaterally miotic pupil size routinely, because a change to dilated and unresponsive indicates a progression of the lesion and the need for immediate medical treatment[39] and carries a grave prognosis. 573

TABLE 10.5-2 Signs Characteristic of Focal Brain Injury

LEVELS	CONSCIOUSNESS	MOTOR FUNCTION	PUPILS	OTHER SIGNS
Cerebrum	Behavior change, depression, coma	Circling	Normal	Blindness
Cerebellum		Ataxia and hypermetria, intention tremor		Menace response deficit without blindness
Diencephalon (thalamus)	Depression to stupor	Normal to mild tetraparesis, “aversive syndrome”[*]	Bilateral, nonreactive pupils with visual deficit	None
Midbrain	Stupor to coma	Hemiparesis; tetraparesis or tetraplegia	Nonreactive pupils, mydriasis, anisocoria	Ventrolateral strabismus
Pons	Depression	Ataxia and tetraparesis, tetraplegia	Normal	Head tilt, abnormal nystagmus, facial paralysis, medial strabismus
Rostral medulla oblongata (including inner ear)	Depression	Ataxia or hemiparesis to tetraplegia	Normal	Same
Caudal medulla oblongata	Depression	Ataxia, hemiparesis to tetraparesis, abnormal respiratory patterns	Normal	Dysphagia, flaccid tongue

From Reed SM: Cranial trauma. In Robinson NE, editor: Current therapy in equine medicine, ed 2, Philadelphia, 1987, WB Saunders.

* Deviation of the head and eyes with circling toward the side of a unilateral lesion.

General physical examination is important in cranial trauma because fractures and other concurrent injuries are common and require identification and treatment. Physical findings resulting from cranial trauma include blood coming from the nostrils, mouth, and ears or CSF draining from the ear (basilar fractures) (Figure 10.5-2).[38,39] With severe head trauma a brain-heart syndrome can develop consisting of cardiac arrhythmias, increased serum levels of heart-specific enzymes, myocardial necrosis, and sudden death from heart failure.[13]

Ancillary diagnostic aids helpful in further defining cranial trauma include radiography and CT to identify fractures and CSF analysis.[14] Cisternal CSF collection is contraindicated if one suspects increased intracranial pressure because of the possibility of brain herniation through the foramen magnum. Lumbosacral collection may be a safer alternative but can be normal despite a traumatic episode, especially in the acute phase, and because the sample is not obtained closest to the lesion, it may not reflect the changes that have occurred.[13] As with spinal cord trauma in human beings, CT and magnetic resonance imaging are also the diagnostic aids of choice in cases of head trauma.[1,48] If available, CT is an invaluable diagnostic aid.

10.5.2.3 TREATMENT AND PROGNOSIS

Based on the pathophysiology of events that occur during TBI, clearly a single-drug intervention for treating 574
TBI is not effective.[42] However, most research studies and pharmaceutical trials follow this single-drug 575
intervention approach. In horses, treatment of TBI aims at reducing brain edema, reducing intracranial pressure, and reducing free radical injury. The use of corticosteroid and DMSO for the reasons discussed under Spinal Cord and Vertebral Trauma are beneficial in treating cranial trauma. The dosages used in horses with intracranial trauma are the same as in spinal cord trauma. The neuroprotective effects of high-dose MPSS treatment also may be applicable to head injury.[24] Further research on the use of MPSS treatment in head trauma patients is needed to verify its usefulness.

Figure 10.5-2 Blood and cerebrospinal fluid draining from the ear following a basilar skull fracture.

Research in human and animal models has demonstrated that following TBI cerebral, mitochondrial function is impaired primarily through effects of ischemic hypoxia. However, the process of mitochondrial damage continues, and mitochondrial impairment may persist for 14 days after injury despite adequate delivery of oxygen and glucose. This indicates that restoring mitochondrial function might be as important as maintaining substrate delivery. Pharmacological interventions in animal models of experimental TBI that have been used to ameliorate mitochondrial function include the use of calcium channel blockers and antioxidants.[44] In horses, treatment aimed at reducing free radical damage is generally through administration of DMSO and vitamin E. However, the fact that lipid peroxidation occurs early on in TBI may be a limiting factor in the efficacy of free radical scavenger pharmacologic therapy.[49] Similar to spinal cord injury, treatment with 21-aminosteroids may be of benefit in TBI.[50] Hypothermia, and subsequent decreased cellular metabolism has been proven efficacious in treatment of TBI in experimental and clinical settings.[51,52] The neuroprotective effects include reduced release of excitotoxins, reduction of free radical and inflammatory mediator formation, and reduction of blood-brain barrier disruption. However, long-term benefits and improved functional outcome has not been demonstrated adequately.[53,54]

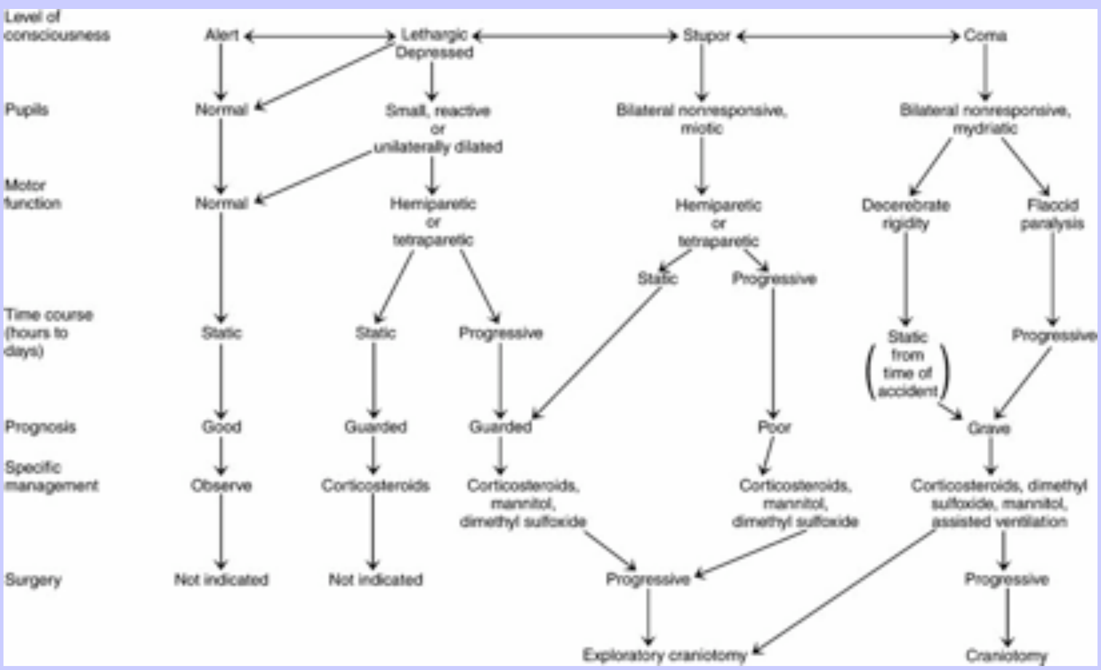
Osmotic diuretics such as 20% mannitol administered at 0.25 to 2.0 mg/kg intravenously over 20 minutes and glycerol administered at 0.5 to 2.0 mg/kg intravenously every 6 to 12 hours for 24 hours are effective in combating cerebral edema and increased intracranial pressure.[13,39] These diuretics have a rapid onset of action (10 to 20 minutes) and work because of their hyperosmolar nature. One should exercise caution in using these compounds because they can cause further hemorrhage by decreasing edema and allowing space for more bleeding. Leakage of these hypertonic solutions into the tissue also may increase cerebral edema.[45] Horses receiving osmotic diuretics should be hydrated adequately. The use of osmotic substances is warranted in any horse with worsening mental status, abnormal pupillary size, or inequality indicating transtentorial herniation, or development of paresis.[48]

Although mannitol administration is effective in reducing intracranial pressure, it has technical limitations for administration. Furthermore, the administration of multiple doses of mannitol may lead to intravascular dehydration, hypotension, and reduction of CBF.[55] Therefore current research focuses on the use of hypertonic solutions that reduce intracranial pressure and support intravascular volume.[56,57] Hypertonic saline administered early to treat shock associated with head trauma may enhance return of cerebral blood flow and cell membrane function.[58] Effects of hypertonic saline are due to its ability to move water out of cells and to decrease tissue pressure and cell size by osmotic plasma expansion.[58,59] These effects result in a lowering of intracranial pressure and cerebral water content. The beneficial effects of hypertonic saline prevail even with subsequent administration of isotonic fluids.[58,60] When 1.8% sodium chloride was compared with hypotonic Ringer's lactate solution as 24-hour maintenance fluids following experimental cerebral injury, the 1.8% saline provided the stated beneficial effects and adequate cardiovascular support, suggesting that hypertonic saline may be the maintenance fluid of choice in head injury.[61] Furthermore, multiple studies using 3% and 7.5% hypertonic saline have demonstrated similar effects on intracranial pressure.[62,63] Another study comparing the effects of a hypertonic saline hydroxyethyl starch solution and mannitol on increased intracranial pressure found that the hypertonic saline hydroxyethyl starch reduced the ICP more effectively than mannitol.[64] Recently, induction of prolonged hypernatremia using 3% hypertonic saline administered as a continuous infusion appeared to be a promising therapy for control of cerebral edema.[57] The authors have found 3% hypertonic saline useful in cases of suspected increased ICP, and furthermore, hypertonic saline is technically easier to administer than mannitol.

Experimentally, furosemide has been found effective in decreasing intracranial pressure. A 1-mg/kg bolus intravenous dose was given at 5-hour intervals, and a 0.5-mg/kg/hr dose was given intravenously for 4 hours, 1 hour after the initial bolus.[65] Normal hydration status is required before furosemide administration. One also may use furosemide concurrently with mannitol to increase the duration of intracranial pressure reduction provided by mannitol and to diminish the potential for rebound intracranial pressure elevation.

Other methods to lower intracranial pressure include elevation of the head by 30 degrees if no cervical fractures are present.[66] Hyperventilation to lower the partial pressure of carbon dioxide to 26 to 28 mm Hg in human beings decreases cerebral blood flow, thus lowering intracranial pressure.[48] One may consider 575
hyperventilation in cases of increased intracranial pressure in horses. Proper hyperventilation requires 577
monitoring of arterial blood gases and may require use of neuromuscular blockers if the horse is not comatose and is resisting the ventilator.

Figure 10.5-3 Flow chart for management of cranial trauma. (From Reed SM: Spinal cord trauma. In Robinson NE, editor: *Current therapy in equine medicine,* ed 2, Philadelphia, 1987, WB Saunders; modified from Kirk KW, editor: *Current veterinary therapy VII,* Philadelphia, 1980, WB Saunders.)



Barbiturate treatment or coma may decrease cerebral metabolism, thereby providing a protective effect against cerebral ischemia.[39,48] Barbiturates also may limit lipid peroxidation.[39] However, the actual benefits of barbiturate use on the neurologic outcome remain controversial. Concurrent hyperventilation enhances the effects of barbiturates on lowering intracranial pressure. An exact dosage regimen for barbiturate treatment in horses has not been investigated, but 5 to 10 mg/kg intravenously to effect is reported to be useful.[40] The

major side effect of barbiturates is hypotension, especially if mannitol and furosemide have been administered, so they must be used with caution and adequate blood pressure monitoring. One should reserve the use of barbiturates for those cases in which elevated intracranial pressure is refractory to other treatments.

Horses with intracranial trauma often need fluid therapy to maintain hydration and blood pressure. Isotonic crystalloid fluids administered in typical shock doses of 40 to 90 ml/kg/hr may produce worsening of cerebral edema and increased intracranial pressure. Comparison of isotonic crystalloid fluids with hypertonic saline solutions for fluid support of head trauma patients in shock has shown hypertonic saline to be the fluid of choice. Hypertonic saline is associated with significant decreases in intracranial pressure and cerebral water content compared with isotonic fluid treatment.[58] One may give hypertonic saline to horses with head trauma and in shock as a 5% or 7% sodium chloride solution in a 4- to 6-ml/kg intravenous bolus over 15 minutes. One then may use isotonic fluids for maintenance if needed. Monitoring central venous pressure to keep it in the normal range of 5 to 7 cm H_2O is important in comatose horses to avoid overhydration. Contraindications to the use of hypertonic saline include dehydration, ongoing hemorrhage, hypernatremia, renal failure, hyperkalemic periodic paralysis, and hypothermia.[59]

One should avoid using carbohydrate-containing intravenous solutions early in the treatment of head trauma patients.[39,67] Glucose suppresses ketogenesis and may increase lactic acid production by the traumatized brain, limiting the availability of nonglycolytic energy substrates.[67] Carbon dioxide liberated from glucose metabolism causes vasodilation and worsening of cerebral edema.[39]

Antibiotic treatment usually is given in cases of head trauma, especially when fractures are involved.[13,39] The presence of hemorrhage increases the possibility of septic meningitis. Broad-spectrum antimicrobials, such as those listed for spinal cord trauma, are effective. Because of the disruption of the blood-brain barrier, other antimicrobials probably penetrate into the central nervous system, and therefore their use also may be efficacious.

For horses sustaining cranial trauma to develop seizures is not unusual. The drug of choice in controlling seizures is diazepam. Doses range from 5 mg (foals) to 25 to 100 mg (horses) intravenously, repeated as necessary to control seizure activity.[13,39] Intractable seizures may necessitate general anesthesia. Agents useful for general anesthesia include guaifenesin, chloral hydrate, barbiturates, and gas anesthesia. One should not use ketamine as part of a balanced anesthesia regimen because it increases cerebral blood flow and intracranial pressure.[67,68]

Adequate nutritional support as discussed for spinal cord trauma also applies to head-injured horses. Additionally, the use of 1 g thiamine administered intramuscularly for 5 days may be of benefit in treating head injuries. Thiamine aids breakdown of lactic acid and is a necessary coenzyme in brain energy pathways.[37]

Emergency surgical treatment (although not commonly performed) is warranted in open cranial fractures and in the face of deterioration despite medical therapy. The surgical techniques for these procedures have been described elsewhere.[69] Once the patient is stabilized, one can consider repair of less life-threatening fractures. Figure 10.5-3 summarizes medical and surgical therapies for cranial trauma.[39]

As with spinal cord trauma, the prognosis for cranial trauma depends on early treatment and is gauged by response to treatment. Basilar fractures and severe brainstem injuries carry a grave prognosis.[38] Recumbency,

tetraparesis, and severe dementia carry a poor to grave prognosis.[39] Time, good nursing care, and adequate nutritional support, especially in the recumbent horse, are vital for a positive outcome.

10.6

10.6—Vestibular Disease

Bonnie R. Rush

The vestibular system is a special proprioceptive system responsible for maintenance of balance and reflex orientation to gravitational forces. This system functions to maintain appropriate eye, trunk, and limb position in reference to movements and positioning of the head.[1,2]

10.6.1

Vestibular Apparatus

The afferent unit of the vestibular system comprises the receptor organ within the inner ear and the vestibulocochlear nerve (the eighth cranial nerve). The vestibulocochlear nerve processes auditory and vestibular input through a common physiologic mechanism. Acoustic stimuli and acceleration forces result in mechanical deformation of hair cells in the cochlea and vestibular receptor organs, which transform physical forces into electric impulses.[3] The inner ear is located in the petrous temporal bone and consists of the bony and membranous labyrinth. The membranous labyrinth is suspended within the bony labyrinth by perilymph, fluid similar to and likely derived from cerebrospinal fluid.[2] The membranous labyrinth comprises the cochlea, the saccule, the utricle, and the three semicircular canals.[4] The cochlea is responsible for auditory functions and has no input to the vestibular system.[5] Endolymph fills the membranous labyrinth and is derived from blood vessels along one side of the cochlea.[2]

The three semicircular canals are oriented at right angles to one another, which allows for detection of rotation in any plane at any angle. At one end of each semicircular canal is a dilation of the canal called the ampulla. A ridge of connective tissue called the crista is located on one side of the ampulla. The internal surface of the crista is lined with hair cells (neuroreceptor cells) and sustentacular cells (support cells) that are oriented perpendicular to the flow of endolymph.[2,6] These cells are covered with a gelatinous protein-polysaccharide material called the cupula, which extends across the lumen of the ampulla.[5] Rotation of the head in any plane causes endolymph to flow in one or more of the semicircular ducts. Each hair cell has 40 to 80 stereocilia and a single modified kinocilium. Movement of endolymph causes the cupula to move across the stereocilia. Deformation of the stereocilia by the flow of endolymph toward the kinocilia results in increased neuronal activity of the vestibular nerve. Inhibition of vestibular neurons occurs with deviation of stereocilia away from kinocilia.[5] The semicircular canals are responsible for dynamic equilibrium and respond only to changing forces such as

acceleration and deceleration but not to constant velocity or stationary positioning.[2] The semicircular canals can detect changing forces at a rate of 1 degree/sec^2.[5]

A similar receptor organ called the macula is located in the wall of the saccule and the utricle. The organ consists of a 2-mm oval plaque of dense connective tissue lined by neuroepithelial cells and covered with a gelatinous substance, termed the *otolithic membrane*. Calcium carbonate crystals called statoconia (otoliths) lie on the
otolithic membrane, and their movement initiates stimulation of the vestibular neurons.[7] The macula sacculi is 579
oriented vertically, and the macula utriculi is oriented horizontally. Gravitational forces continuously affect the 580
position of otoliths in at least one of the maculae, supplying constant information regarding the static position of the head.[8] These receptor organs can detect changes in head position of one-half degree from the stationary plane.[5] The maculae of the saccule and utricle also detect linear acceleration and deceleration and are responsible for maintenance of static equilibrium.[8]

The hair cells of the crista ampullaris and maculae synapse with sensory neurons of the vestibular nerve. The cell bodies of these bipolar neurons are located within the petrous temporal bone and constitute the vestibular ganglion.[5] Axons leave the petrous temporal bone through the internal acoustic meatus adjacent to the cochlear portion of the eighth cranial nerve. Fibers course to the lateral aspect of the rostral medulla and penetrate the brainstem between the caudal cerebellar peduncle and the spinal tract of the trigeminal nerve. The majority of fibers of the eighth cranial nerve terminate in the four vestibular nuclei (rostral, medial, lateral, and caudal) located in the lateral wall of the fourth ventricle of the rostral medulla oblongata.[1] Some of these fibers form the vestibulocerebellar tract and directly enter the caudal cerebellar peduncle to terminate in the fastigial nucleus and flocculonodular lobes of the cerebellum. The afferent supply to the vestibular nucleus is primarily from the maculae, the crista ampullaris, and the cerebellum. These sensory fibers synapse with second-order neurons in the vestibular nuclei that extend fibers to the motor neurons of the spinal cord, the nuclei of the cranial nerves that control eye position, the cerebellum, the autonomic nervous system, the reticular formation, and the cerebral cortex.[2,5]

The vestibulospinal tract courses in the ipsilateral ventral funiculus and terminates in interneurons of the ventral gray column. Stimulation of the vestibulospinal tract is facilitatory to α- and γ-motor neurons of the ipsilateral extensor muscles, inhibitory to the α-motor neurons of the ipsilateral flexor muscles, and inhibitory to contralateral extensor muscles.[2] The net result is ipsilateral extensor tonus and contralateral flexor tonus that act as an adaptive mechanism against gravity by catching the body and preventing a fall in the direction of vestibular stimulation.[6]

Axons from the medial vestibular nucleus project through the medial longitudinal fasciculus. The ascending portions of the medial longitudinal fasciculus course to the motor nuclei of the third, fourth, and sixth cranial nerves (oculomotor, trochlear, and abducens).[4,9] These fibers coordinate conjugate eye movement with changes in head position. This pathway, along with cerebellar input, controls physiologic (vestibular) nystagmus.[2] Physiologic nystagmus is a normal reflex that allows the eyes to remain fixed on a stationary object while the head moves.[5] Nystagmus is characterized by involuntary, conjugate, rhythmic eyeball oscillations with a fast and slow phase. The direction of nystagmus is defined by the direction of the fast phase and is induced by rapid movements of the head. Rapid dorsiflexion of the neck results in vertical nystagmus, whereas side-to-side movement of the head induces horizontal nystagmus. Turning the head to the left results in a horizontal nystagmus with the fast phase to the left. The accompanying slow phase is in a direction opposite to body motion and allows the eyes to fix on a stationary image. The fast phase is initiated when the eyeball reaches the lateral

limit of ocular movement and allows the eyeballs to jump forward and focus on a new image.[5,6] The slow phase is controlled by vestibular input, and the fast phase is a function of the brainstem.[2] Physiologic nystagmus induced by rapid manipulation of the head is called the oculocephalic reflex. This reflex occurs independent of vision.[10] Descending portions of the medial longitudinal fasciculus travel in the ventral funiculus of the cervical and cranial thoracic spinal cord segments and control the position and activity of the limbs and trunk in coordination with head position.[2,5]

Fibers from the vestibular nuclei that project to the reticular formation provide afferent nerves to the vomit center, which is the pathway for the development of motion sickness. Reticulospinal tracts also aid in the maintenance of extensor tone to support the body against gravity.[2,5]

Vestibular impulses enter the cerebellum via the caudal cerebellar peduncles. Fibers of the vestibulocerebellar tracts terminate primarily in the flocculonodular lobe and fastigial nucleus.[2] The flocculonodular lobe appears to be linked closely to the semicircular canals in the control of dynamic equilibrium.[5] The cerebellum functions to coordinate protagonistic, antagonistic, and synergistic muscle groups for controlled responses to gravity. The vestibular apparatus provides information to the cerebellum, dictating the relative degree of contraction necessary to maintain equilibrium.[5]

Vestibular signals travel through to the contralateral medial geniculate nuclei of the thalamus to the cerebral cortex. In addition to proprioceptive information from other parts of the body, the cerebral cortex facilitates conscious perception of orientation.[2]

The vestibular system is capable only of detecting movement and orientation of the head in relationship to the rest of the body. Afferent pathways from the neck allow the head to be cognizant of the orientation of the rest of the body.[5,8] Proprioceptive receptors in the joints of the neck that transmit signals to the reticular formation are essential to the righting reflex.[7,8] Exteroceptor receptors of the skin and proprioceptive receptors in other joints also are integrated in the cerebellum and reticular formation to aid in the maintenance of equilibrium. These 580
signals allow the vestibular system to know if the body remains in an appropriate position with respect to gravity 581
while the head is bent. Visual images can help to maintain balance by visual detection of the upright stance. In addition, slight linear or angular movement of the head shifts the image on the retina, which relays directional information to equilibrium centers. Visual compensation may be capable of maintaining balance in the face of complete vestibular destruction, if the eyes are open and motions are performed slowly.[5]

The seventh cranial nerve (the facial nerve) emerges from the lateral medulla ventral to the vestibulocochlear nerve at the level of the trapezoid body. The two nerves are associated closely with the petrous temporal bone and enter the internal auditory meatus together.[11] Within the internal auditory meatus, the facial nerve separates from the vestibular nerve and courses through the facial canal of the petrosal bone. The facial nerve exits the cranium from the stylomastoid foramen located immediately caudal to the external auditory meatus. Both nerves commonly are affected simultaneously by a single disease process because of the proximity of the facial and vestibular nerves.[12]

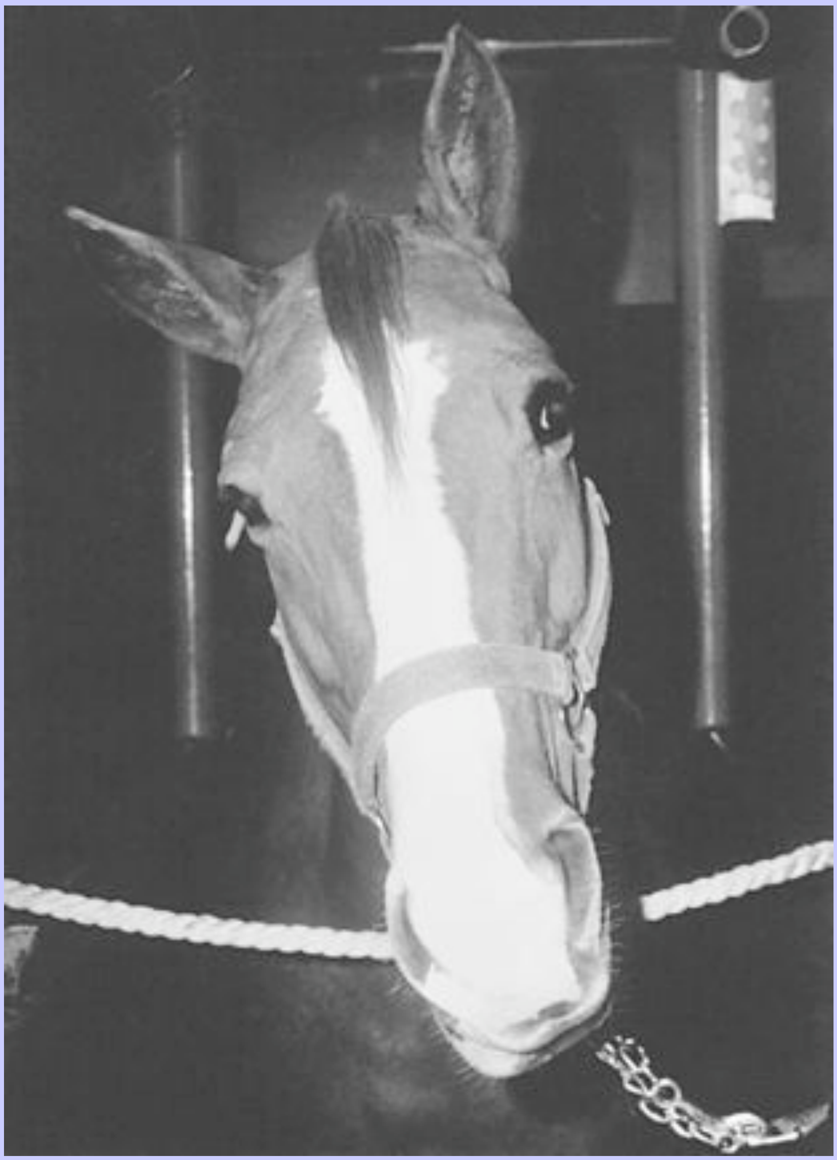
Sympathetic innervation to the eye also is associated anatomically with the petrous temporal bone. Damage to this nerve (Horner's syndrome), along with vestibular and facial nerve deficits, frequently occurs with petrous temporal bone trauma and otitis media in small animals.[10] The association of Horner's syndrome, facial nerve paralysis, and vestibular disease rarely is documented in the horse.[2]

10.6.2 Clinical Signs

Knowledge of the anatomy and function of structures related to the peripheral and central vestibular system aids in neuroanatomic localization of the lesion.[10] Differentiation of central versus peripheral vestibular disease is important for establishing a list of differential diagnoses, initiating therapy, and formulating a prognosis. A thorough physical and neurologic examination of a horse with vestibular disease may identify nonvestibular neurologic signs, lending significant insight into the location of the lesion. Historical information, including duration of condition, rate of onset, and disease progression, also may aid in differentiation of central from peripheral vestibular disease.

Signs of acute peripheral vestibular system dysfunction include head tilt, nystagmus, falling, circling, reluctance to move, and asymmetric ataxia with preservation of strength.[*] Horses affected with peracute vestibular disease are often violent because of disorientation.[1] A true head tilt is a consistent sign of vestibular disease and is characterized by ventral deviation of the poll of the head toward the affected side[4,14] (Figure 10.6-1). The horse prefers to lie on the side of the lesion and may lean on the wall toward the affected side when standing. When forced to move, the horse takes short, uncoordinated steps in a circle toward the direction of the lesion. The body may be flexed laterally with a concavity toward the lesion.[4,6] Extensor hypotonia ipsilateral to the lesion and mild hypertonia and hyperreflexia of the extensor muscles of the contralateral side result in asymmetric ataxia.[15] Extensor hypotonia occurs from loss of facilitatory neurons of the vestibulospinal tract to ipsilateral extensor muscles. Contralateral extensor hypertonia occurs from loss of inhibitory neurons and unopposed extensor tone of the contralateral vestibulospinal tract.[2,6,14] Central vestibular disease has similar clinical signs, but general proprioceptive deficits, weakness, and multiple cranial nerve deficits also may be present, resulting from damage to the surrounding neurologic structures. The onset of vestibular signs in a horse with an expanding space- 581
occupying central lesion is not as dramatic as peripheral nerve damage; adjustments by compensatory 582
mechanisms occur during slow development of the lesion. These lesions, however, are not likely to show significant clinical improvement after the onset of clinical signs, as may occur with peripheral vestibular lesions.

Figure 10.6-1 Thoroughbred with right-sided peripheral vestibular disease caused by a pathologic fracture of the petrous temporal bone following otitis media-interna. The head tilt, dropped pinna, and eyelid droop occur on the affected side, whereas the muzzle is pulled toward the contralateral side.



Pathologic nystagmus is involuntary, rhythmic oscillations of the eyes occurring while the head is in a normal position and indicates a lesion in the vestibular system or cerebellum.[12] As in physiologic nystagmus, one can identify a fast and a slow phase. The direction of nystagmus is defined by the direction of the fast phase.[2,5,12] Pathologic nystagmus may be spontaneous, occurring with the head in the resting position, or positional, which

is induced by elevation or lateral flexion of the head.[2] Nystagmus usually appears with the onset of other peripheral vestibular signs but may last only 2 to 3 days because of central compensation.[4,15] Concomitant blinking of the eyelid may hinder detection of nystagmus.[2]

Peripheral vestibular dysfunction may result in horizontal or rotary nystagmus. The fast phase of nystagmus is directed away from the lesion and does not change with changing head position.[2,3,6] The direction of rotary nystagmus is defined by the direction the limbus moves from the 12 o'clock position during the fast phase.[2] Horizontal, rotary, or vertical nystagmus can result from a central vestibular lesion. In addition, the type of nystagmus observed may change with changing head position in a patient with central vestibular disease.[1,12,14] Often the fast phase is directed away from the central lesion, but this is not a consistent finding.[2]

In the healthy animal a constant stream of electric stimulation arises in each vestibular end organ and transmits signals that control ocular position via the medial longitudinal fasciculus. These signals normally drive the eyes toward the opposite direction. The eyes are maintained centrally, however, because vestibuloocular pathways are opposed in an equal and opposite manner. Unilateral vestibular disease upsets this balance, resulting in slow deviation of both eyes toward the lesion. Rapid eye movements return the eyes to midposition. Individuals that are blind at birth or have been blind for an extended time may exhibit irregular eyeball oscillation with no slow or fast component.[16]

Ataxia and dysmetria are often severe with peripheral vestibular disease; however, strength is maintained. Postural reactions remain normal with the exception of the righting reflex. The motor system is unable accurately to control movement and identify the location of different parts of the body at a given time. Therefore the horse makes an exaggerated response toward the side of the lesion as it attempts to stand.[2]

Loss of hearing is a common finding with peripheral vestibular disease because of the proximity of the cochlea to the vestibular receptor organs. In the central nervous system, diffuse pathways control auditory signals and extensive central disease would be necessary to cause hearing loss.[14]

If vestibular signs are accompanied by depression, weakness, or conscious proprioceptive deficits, a central vestibular system lesion is likely. With a central lesion, abnormal conscious proprioception occurs because of damage within the brainstem of the descending upper motor neuron tracts to the limbs.[2] Damage to the spinocerebellar tracts or caudal cerebellar peduncles results in abnormal unconscious proprioception and hypermetria.[1] The nuclei of the trigeminal (fifth cranial nerve) and the abducens nerves (sixth cranial nerve) are in anatomic proximity to the vestibular nuclei and are damaged readily in a common disease process. Trigeminal nerve paralysis creates a loss of sensation to the head and atrophy of the muscles of mastication. Trochlear nerve damage results in medial strabismus.[10]

Destructive space-occupying lesions in the cerebellopontine angle or flocculonodular lobe may result in paradoxical central vestibular disease.[1,17] This syndrome is manifested by vestibular ataxia and a head tilt contralateral to the side demonstrating general proprioceptive ataxia and postural reaction deficits. When this unusual combination of neurologic signs is present, localization of the lesion is defined by the side of general proprioceptive deficits.[2,10]

Central or peripheral vestibular disease may produce strabismus. One observes ventrolateral strabismus ipsilateral to the vestibular lesion with elevation of the head and extension of the neck.[2,10] One observes mild ventral deviation of the eyes in normal horses when the head is elevated, but the finding is symmetric.

Ventrolateral strabismus of vestibular disease is not a sign of a cranial nerve deficit of the extraocular muscles[2] but is a reflection of abnormal upper motor neuron influences on the oculomotor nucleus from the ipsilateral vestibular nucleus via the medial longitudinal fasciculus. If the strabismus is purely vestibular in origin, normal ocular mobility is visible with manipulation of the head.[14]

Signs of vestibular disease may improve rapidly 2 to 3 weeks after onset because of visual and central accommodation.[2,13] Central vestibular lesions are slower to compensate than peripheral vestibular lesions; signs may even progress if the central lesion is an expanding space-occupying mass.[14] Human beings compensate satisfactorily for unilateral disease but are not required to be coordinated athletes performing at high speed.[4] Blindfolding a horse with compensated disease results in ataxia and a head tilt (Romberg's test). Blindfolding eliminates visual and limb proprioceptive orientation; the body is forced to rely on the impaired vestibular system for equilibrium.[2,10,11] This test is unreliable for localizing the side of the lesion.[3] Horses may 582
decompensate dramatically when the blindfold is placed over the eyes, resulting in anxiety, disorientation, and 583
falling.[2] One should perform the test with caution on a padded surface with good footing.

Horses affected with bilateral peripheral disease demonstrate no head tilt, circling, or pathologic nystagmus, and one cannot induce physiologic nystagmus by rapid manipulation of the head (the oculocephalic reflex) or by caloric testing. The head may sway with wide excursions from side to side.[4] As with all peripheral vestibular disease, strength is preserved.[2] Clinically, horses affected with bilateral vestibular disease exhibit more symmetric ataxia similar to generalized cerebellar disease.[1]

Facial nerve (seventh cranial nerve) paralysis frequently occurs concurrently with peripheral vestibular disease because of its proximity to the vestibular nerve within the petrous temporal bone. Facial nerve paralysis worsens the long-term prognosis and complicates the management of vestibular disease patients. The facial nerve innervates the muscles of facial expression, and damage to this nerve results in muzzle deviation away from the affected side, lack of menace and palpebral response, ear droop, decreased nostril flare impeding air flow, and buccal impaction of feed.[4,11,12] Keratitis and corneal ulceration are common because of the inability to blink and decreased tear production.[4,18] Decreased tear production results from damage to parasympathetic fibers to the lacrimal gland. Preganglionic fibers travel with the facial nerve through the internal auditory meatus and separate in the facial canal proximal to the geniculate nucleus.[12] The fibers split from the facial nerve to join the superior petrosal nerve, which carries fibers to the sphenopalatine ganglion. Postganglionic fibers join the sympathetic fibers to the eye and travel with the vasculature to the lacrimal gland.[2,12] Corneal ulcerations occur in the inferior portion of the cornea and are slow to heal because of ongoing exposure.[11] Lack of tear production aids in localization of the lesion, indicating the damage is within the petrous temporal bone, proximal to the geniculate nucleus.[2,12] Clinical signs of facial nerve paralysis may not appear for several days after the onset of vestibular disease, because damage to the nerve may result from hematoma, callus, or an extension of inflammation and secondary neuritis.[4] Because of the proximity of the nuclei of the facial and vestibular nerves, extensive lesions of the medulla may involve both nerves. If no improvement of facial nerve deficits occurs within 3 to 4 months after the onset of disease, the prognosis is poor for recovery. If one notes even mild improvement in the first 4 months, facial nerve function may return.[4] Horses may learn to retract the globe, allowing the eyelid and nictitating membrane to slide across the surface of the cornea, distributing lubrication and protecting the eye from trauma.[11] Careful observation is necessary to differentiate this adaptation from improvement of lid function.

10.6.3

Peripheral Vestibular Disease

Acute onset of peripheral vestibular disease and facial nerve paralysis is not a rare occurrence in the horse.[15,19] Damage to the temporal bone is the most likely anatomic location when these nerves are affected concurrently. Otitis media-interna and traumatic skull fractures are the most common causes of these signs in large animals.[1]

10.6.3.1

OTITIS MEDIA

Otitis media-interna is less common in the horse compared with other species.[4] The disease occurs in adult horses with no breed or sex predilection. Rupture of the tympanic membrane and drainage of exudate from the external meatus can occur in the horse but is uncommon.[11,15] Instead, as in lambs the infectious process migrates ventrally, creating chronic inflammation of the tympanic bulla and proximal stylohyoid bone.[20] Inflammation induces bony proliferation of these bones with loss of the joint space and fusion of the temporohyoid joint. The hyoid apparatus is linked in series to the tongue and larynx; fusion of the temporohyoid joint results in impaired flexibility of the unit. A stress fracture of the petrous temporal bone, the stylohyoid bone, or both may result from eating or vocalization with normal tongue movement.[6,15] Petrous temporal bone fracture is most common. The fracture line extends into the cranial vault at the level of the internal auditory meatus, resulting in direct neural tissue trauma and hemorrhage into the middle and inner ear.[1,15] No neurologic signs are apparent during the formation of proliferative osteitis and temporohyoid joint fusion. The onset of neurologic signs corresponds with the occurrence of the stress fracture. Occasionally, the fracture extends to the foramen lacerum, caudal to the petrous temporal bone, where the glossopharyngeal and vagus nerves exit the skull. Trauma to these nerves by the fracture may result in dysphagia for several days, in addition to acute vestibular disease.[11]

As a result of extension of the inflammation through the internal acoustic meatus, focal suppurative meningitis may occur at the level of the pons, resulting in fever and depression.[21] Secondary meningitis complicates the treatment and management and worsens the prognosis for recovery.[15]

The origin of the infectious process of otitis media is presently unknown. Extension from otitis externa and tympanic membrane rupture is unlikely.[21] Hematogenous spread of bacteria to the inner ear and ascending infection from the eustachian tube are highly suspected.[4,11,15,21] Acute vestibular disease resulting from 583
extension of an aspergillosis guttural pouch infection to the stylohyoid and petrous temporal bone has been 584
documented.[22] However, otitis media rarely is associated with concurrent guttural pouch infection. In addition, microorganisms isolated from the guttural pouch did not correlate with microorganisms obtained from the middle ear of normal horses.[1,18] Pathogenic organisms isolated from the middle ear of horses include *Actinobacillus, Salmonella, Enterobacter, Pseudomonas, Streptococcus, Staphylococcus,* and *Aspergillus*.[1,18]

Radiographic examination of the skull is necessary for establishing the diagnosis of osteitis. Dorsoventral radiographs are most valuable in identifying the characteristic periosteal proliferation and sclerosis of the stylohyoid bone and petrous temporal bone[4,11,18] (Figure 10.6-2). The fracture line is difficult to identify because of minimal displacement of the fracture fragments, and lateral oblique radiographs at varying angles may aid in localization of a petrous temporal bone fracture. Several acute onset cases of otitis media initially did not demonstrate characteristic radiographic evidence of disease. Moderate bony proliferation may not

occur for several weeks and must be present to diagnose the condition radiographically.[18] Bone scintigraphy is a noninvasive technique that may allow for an immediate identification of early lesions of the petrous temporal bone. Radiography can identify only structural abnormalities of bone. Bone scintigraphy is capable of detecting dynamic characteristics of bone. Increased metabolic activity and blood supply to the bone, caused by infection or fracture, results in increased uptake of the radiolabeled compound (technetium-99m–labeled phosphate) before radiographic evidence of bony proliferation.[23–25]

Figure 10.6-2 Ventrodorsal skull radiograph demonstrating bony proliferation of the proximal left stylohyoid and petrous temporal bones *(arrows)* following chronic otitis interna-media.

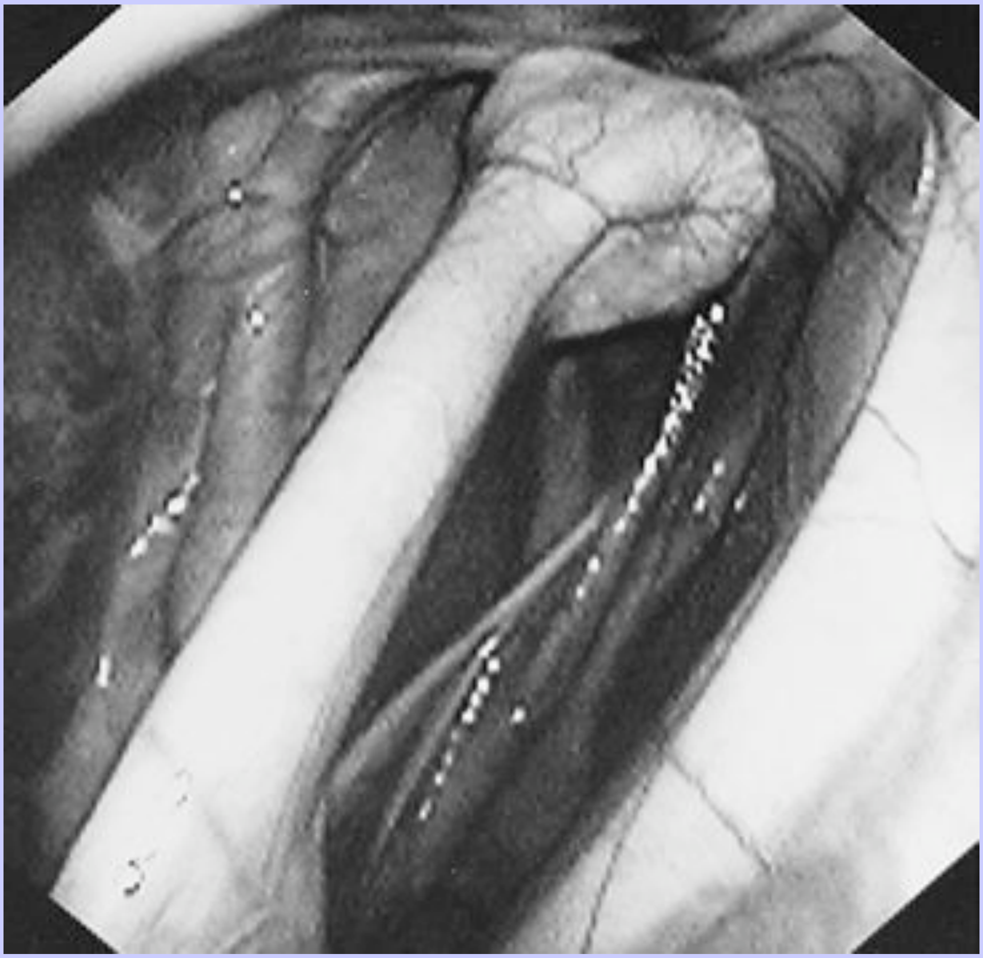
Otoscopy is difficult in the horse because of the long, bony, narrow, horizontal ear canal. The accumulation of ceruminous debris also impedes visualization.[12,18] Anesthesia allows for complete cleaning of the external auditory canal and is likely to be necessary for a thorough otoscopic examination given the uncooperative nature of the awake horse. Even with a thorough examination, detecting subtle changes of the tympanic membrane is difficult. Transtympanic lavage may aid in the diagnosis of otitis media. One infuses sterile saline (0.5 ml) via a myringotomy with immediate withdrawal of fluid. A cloudy or yellow tap is a positive finding. Fluid is submitted for cytologic examination, protein evaluation, and culture. Anaerobic and aerobic culture and sensitivity may allow for identification of the pathogenic organism and aid in appropriate antibiotic selection.[18]

One should perform cerebrospinal fluid analysis in all cases of acute vestibular disease.[1,2] In the case of otitis media, cerebrospinal fluid analysis, culture, and sensitivity help to reveal the presence of secondary bacterial meningitis, identify the causative organism, and direct the selection of an appropriate antibiotic.[15]

Endoscopy of the pharynx and guttural pouch is generally diagnostic in horses with proliferative osteitis of the stylohyoid bone. One should perform this noninvasive procedure on every horse suspected of having proliferative osteitis, because one often can identify bony proliferation of the proximal stylohyoid bone within the guttural pouch[1,22] (Figure 10.6-3).

Treatment should include long-term administration (30 days) of broad-spectrum antibiotics. Potentiated sulfa, 2 mg/kg ampicillin administered intramuscularly b.i.d. or t.i.d., and 15 to 25 mg/kg chloramphenicol administered orally q.i.d. have been recommended when one cannot obtain culture and sensitivity tests.[11,15] Two to 4 mg/kg phenylbutazone administered orally b.i.d. helps alleviate inflammation. If one identifies central nervous system involvement, 1 g/kg dimethyl sulfoxide administered intravenously in 10% solution is recommended to reduce brain inflammation and edema.[1] One should avoid corticosteroid therapy if one suspects an infectious process. Intensive supportive care and topical therapy for corneal ulceration also may be necessary. 584

Figure 10.6-3 Endoscopic view of the right guttural pouch of a horse with acute onset of right-sided vestibular disease and facial nerve paralysis. Bony proliferation of the proximal stylohyoid bone is consistent with chronic osteitis caused by otitis interna-media.



Diagnosis before acute neurologic signs is difficult because most horses may exhibit no clinical signs. Some horses may demonstrate early signs of otitis media, including ear rubbing, head tossing, chomping movements, and ear sensitivity before the onset of neurologic signs. Affected horses may exhibit signs of pain on palpation at the base of the ear. Head tossing is a common problem in the horse, with multiple causes; the primary problem rarely is identified.[18] One should perform ventrodorsal radiographs of the skull and endoscopy of the guttural pouches on the head-shaking horse to identify an early case of otitis media. Surgical removal of a 2-cm segment of the stylohyoid bone has been attempted on several head-shaking horses with bony proliferation of the petrous temporal bone in an attempt to prevent secondary stress fracture and neurologic signs. A fibrous nonunion of the stylohyoid bone should interrupt the transmission of hyoid forces to the temporohyoid joint. Long-term success of the surgery has not yet been established.[18]

10.6.3.2

HEAD TRAUMA

Traumatic fractures of the petrous temporal bone result in damage to the vestibular and facial nerves. Profuse aural hemorrhage or loss of cerebrospinal fluid from the external ear canal frequently is observed. Bleeding from the nose occurs if the fracture extends to the cribriform plate.[4] Clinical signs usually appear immediately following trauma and include vestibular disease, facial nerve paralysis, recumbency, or coma. Damage to nervous tissue may be caused by hematoma, callus formation, or displacement of fracture fragments resulting in delayed onset of clinical signs. Signs from brainstem contusion or concussion may be more severe than vestibular dysfunction. If blindness is present, the prognosis worsens because of the loss of visual compensation of vestibular disease in the future. If one cannot elicit the oculocephalic reflex (physiologic nystagmus), one should suspect damage to the medial longitudinal fasciculus, indicating extensive brainstem damage; a poor prognosis is indicated.[2] One may recall that bilateral peripheral vestibular disease also results in loss of the oculocephalic reflex; this, however, is an unlikely scenario for trauma.

Fractures of the basioccipital and basisphenoid bones occur most frequently in horses that rear over backward and strike the poll of the head. This fracture does not result from referred impact from the poll but is thought to be an avulsion fracture from the pull of the powerful ventral straight muscle of the neck (rectus capitis ventralis) on its insertion on the basioccipital bone.[26] Basioccipital fractures result in neurologic signs associated with damage to the brainstem; signs of vestibular disease are common.

Petrous temporal bone fractures are difficult to identify radiographically; tympanosclerosis appears as early as 20 days after trauma and obscures the fracture line.[4] One often can identify basioccipital fractures easily but can confuse them with the suture lines in the base of the skull.[26]

Treatment of vestibular signs following head trauma is similar to that of otitis media. Antiinflammatory drugs such as phenylbutazone and dimethyl sulfoxide are indicated to reduce swelling and edema. Broad-spectrum antibiotics are required to prevent secondary bacterial infection. One should administer dexamethasone intramuscularly at 0.1 to 0.2 mg/kg every 4 to 6 hours for 1 to 4 days if one suspects brain concussion or contusion.[1] Acepromazine maleate lowers the seizure threshold and is contraindicated in cases of head trauma.[27] Xylazine may potentiate an active bleeding process because of transient hypertension and should be avoided in the early period following head trauma.[28]

Drug toxicities can result in unilateral or bilateral peripheral vestibular disease and deafness. Degeneration of the hair cells within the peripheral receptor organs of the auditory and vestibular system occurs with prolonged administration of aminoglycoside antibiotics. Severely affected animals also develop neural degeneration.[3] A more common manifestation of aminoglycoside toxicity is renal failure. As renal clearance of the aminoglycoside decreases, the ototoxic effects of the antibiotics are potentiated.[1,10,21] Clinical signs of 585
vestibular disease appear before deafness. Early vestibular disease may be reversible or centrally compensated, 586
but loss of auditory function is permanent.[2,10,21] Streptomycin preferentially affects the vestibular system, whereas dihydrostreptomycin, kanamycin, gentamicin, neomycin, and vancomycin are more toxic to the auditory system.[2,15] Vincristine, a vinca alkaloid, can cause bilateral cochlear nerve damage in human beings. Auditory function improves several months after discontinuation of the drug.[3] This antimitotic drug is a common component of multiagent chemotherapy protocols in the treatment of lymphosarcoma in the horse.[29]

Vincristine also is used for immunosuppression and stimulation of platelet function in refractory cases of immune-mediated thrombocytopenia.[30] One should carefully monitor auditory function when using this drug.

Sudden loud noises can result in degeneration and necrosis of the sensory hair cells of the inner ear.[21] A lightning strike, although usually fatal, is reported to cause acute onset of unilateral vestibular disease in the horse. Facial nerve paralysis may or may not accompany the vestibular signs. Documentation of histopathologic findings in one case revealed hemorrhage and necrosis of the temporal bone, vestibular nerve, and adjacent tissue. Whether the mechanism of damage is electrocution or noise trauma is unknown.[1]

10.6.4 Central Vestibular Disease

Any inflammatory disease or space-occupying mass of the central nervous system may damage the vestibular nuclei and related tracts. Clinical signs vary with the type and extent of the disease process. One should suspect a central nervous system disease if abnormal mentation, seizures, blindness, or multiple cranial nerve abnormalities with general proprioceptive deficits are present. One should perform an electroencephalogram to detect the location and extent of the central nervous system lesion. The electroencephalogram can detect only cerebral damage and cannot identify lesions of the brainstem. Inflammatory, parasitic, and neoplastic diseases have been implicated in central vestibular disease of the horse.

Inflammatory disease affecting the central nervous system includes bacterial abscess, equine protozoal myelitis, polyneuritis equi, and viral encephalitis. One should perform cerebrospinal fluid analysis to identify the inflammatory process. In the case of brain abscessation a culture of the cerebrospinal fluid may identify the causative organism; *Streptococcus equi* is a common causative agent.[32,33] Equine protozoal myeloencephalitis is a common neurologic disease in the United States and Canada and should be suspected if multifocal disease is present.[1] For polyneuritis equi to occur with vestibular dysfunction is common, but the signs of cauda equina neuritis predominate.[2] Rabies may present as an encephalitis or spinal cord disease and should be considered in the differential diagnosis of any horse with neurologic disease. Spinal ataxia is the primary neurologic deficit observed in horses affected with equine herpesvirus myelitis, but the presence of concurrent vestibular disease is reported.[34] The major clinical signs observed with a togavirus (eastern, western, and Venezuelan equine encephalitis) infection are depression and seizure, although cranial nerve deficits are observed.[6,33]

Aberrant parasite migration of the central nervous system in horses results in acute onset of neurologic signs. Clinical signs vary, but progression of clinical signs occurs in most instances. Neurologic signs are generally asymmetric because of the random nature of migration. The parasites most frequently identified are *Hypoderma, Habronema, Strongylus,* and *Setaria* species. *Strongylus vulgaris* is most common and also may produce parasitic thromboembolism to the brain.[1,33] Migration of *Micronema deletrix* and *Setaria* may produce severe, diffuse brain and spinal cord disease.[35] Cerebrospinal fluid analysis may reveal eosinophilic or neutrophilic leukocytosis with evidence of hemorrhage. *Micronema* may be identified in the cerebrospinal fluid and urine.[1] Treatment includes antiinflammatory (flunixin meglumine, phenylbutazone, dexamethasone) and antiparasitic drugs (ivermectin, 200 mg/kg; fenbendazole, 50 mg/kg/day for 1 to 3 days; thiabendazole, 440 mg/kg s.i.d. for 2 days). Recovery may be dramatic.[1] Fungal granulomata caused by *Aspergillus* and *Cryptococcus neoforman* s have been reported as space-occupying masses within the cranium of a horse.[1,36] Cholesteatoma (cholesterol granuloma) could involve the vestibular system by extending from the choroid plexus of the fourth ventricle of the brain.[1] Neoplastic diseases of the central nervous system are rare in the horse. Any tumor affecting the

cerebellomedullary angle could result in vestibular signs.[2] Lymphosarcoma, ependymoma, meningeal melanoma, and melanotic hamartoma have been reported to affect the central nervous system of the horse.[2,37]

10.6.5 Ancillary Diagnostic Tests

10.6.5.1 CALORIC TESTING

The caloric test is a diagnostic aid that may be helpful in differentiating central from peripheral vestibular disease. The test is able to assess each peripheral vestibular sensory organ separately. In the normal animal, irrigation of ice-cold water (12° C) into the external auditory canal for 3 to 5 minutes induces a horizontal nystagmus with the fast phase away from the tested labyrinth.[2,3,5,6] The water cools endolymph closest to the tympanic membrane, increasing its density. A density gradient is created within the semicircular canal and the 586
cooled endolymph sinks, causing displacement of the hair cells. Warm water (45° C) irrigation of the external 587
auditory canal results in horizontal nystagmus with a fast phase toward the tested labyrinth. The warm water test is less reliable.[10,16] The test does not induce nystagmus in a nonfunctional labyrinth. Animals may resist the procedure, making the test difficult to interpret, and in some animals, one cannot induce nystagmus. If one obtains an asymmetric response, the depressed reaction indicates the abnormal labyrinth.[2] The test is difficult to perform and not entirely reliable, although it may be a helpful diagnostic aid in the anesthetized or comatose horse.[6]

10.6.5.2 BRAINSTEM AUDITORY EVOKED RESPONSE

The cochlea is damaged by trauma or inflammation of the peripheral vestibular receptor organs, and detection of hearing loss may help to differentiate central from peripheral vestibular disease. Unilateral hearing loss is difficult to assess subjectively in the horse. Brainstem auditory evoked response is a method of objective assessment of auditory function in the horse. This noninvasive, electrodiagnostic test stimulates the auditory system with a series of clicks. Far-field potentials of the brainstem auditory components are recorded via cutaneous electrodes and a signal averaging system.[6,38] The response is a series of evoked potentials occurring within 10 ms after the stimulus. In the horse the evoked potentials appear on the oscilloscope as a series of five waveforms.[39] In human beings, five to seven waveforms are present, and each corresponds to a specific neurologic structure.[38,39] Abnormalities of the specific waveforms can identify a lesion of the corresponding neurologic structure. In the horse, functional loss of the cochlea or eighth cranial nerve results in the loss of the entire waveform on the side of injury, and the presence or absence of the waveform can differentiate a central from a peripheral vestibular lesion. The test is reliable with sedation and general anesthesia. General anesthesia is not necessary to perform the test, but sedation is recommended.[38]

10.7—Diseases of the Cerebellum

Barbara A. Byrne

587

588

Cerebellar abnormalities have been reported in horses and are confined primarily to a small number of breeds. The cerebellum is essential for the coordination of movement. Afferent information arises from the general and special (vestibular) proprioceptive systems and the special somatic (auditory and visual) systems. The cerebellum is responsible for regulation of the rate, range, and strength of movement, as well as integration and coordination for balance and posture. Cerebellar abnormalities in horses are unusual; however, when present, they can have a profound affect on gait and posture.

10.7.1

Structure and Function

Knowledge of the structure and development of the cerebellum is important for understanding cerebellar function in health and disease. The cerebellum is located in the metencephalon dorsal to the pons and is attached

to the pons via three cerebellar peduncles (Figure 10.7-1). The caudal peduncle is composed primarily of afferent fibers arising from the medulla, the vestibular nuclei via the vestibulocerebellar tracts, and the spinal cord via the spinocerebellar tracts. The middle cerebellar peduncle contains only afferent fibers to the cerebellum that arise from the transverse fibers of the pons. The rostral cerebellar peduncle is the primary connection to the mesencephalon and carries the majority of cerebellar efferent fibers, although a few afferent fibers arise from the spinocerebellar tracts. The cerebellum consists of two hemispheres and a central region known as the vermis.[1] The extensive convolutions of the cerebellar cortex are termed *folia*. The cortex covers the surface of the cerebellum. On cut section, the cerebellar medulla is a central region of white matter with multiple projections called arbor vitae. These branches extend to the cerebellar cortex and form the white matter portion adjacent to the cerebellar cortex.

The cerebellar medulla has three nuclei: the fastigial, interpositional, and lateral nuclei from medial to lateral on each side of the cerebellum. The cerebellum also can be divided into three bilateral longitudinal regions in association with these nuclei.[1,2] The medial zone, containing the vermis and the fastigial nucleus, primarily regulates the tone, posture, and equilibrium of the body in general. The intermediate zones contain the interpositional nucleus and cortex adjacent to the vermis and adjust the orientation of limbs in space, maintaining balance, posture, and muscle tone during complex movements. The lateral zones, consisting of the lateral nuclei and lateral portions of the cerebral hemispheres, have a similar function but do not influence posture or muscle tone directly.[2]

The cerebellum arises from the alar plate region of the metencephalon and originates initially as a proliferation of cells in the rhombic lip that extend dorsally and medially to form the dorsal portion of the metencephalon. Germinal cells proliferating in the rhombic lip eventually migrate into the cerebellum and differentiate to form the specialized neurons of the cerebellar cortex. The cerebellar cortex has three layers: the outer molecular, the middle Purkinje, and the inner granular (Figure 10.7-2). The molecular layer is acellular and consists primarily of the dendritic zones of the Purkinje cells and axons of the granular cells.[1] The Purkinje layer is only one cell thick and consists of Purkinje neurons. The granular layer is densely cellular with granular neurons. All layers must be present and aligned in proper orientation for normal function.

Organization of the specialized structure of the cerebellar cortex allows integration and coordination of movement. The cerebellum primarily provides regulation of skeletal movement, allowing coordinated movement; it does not initiate muscular activity. Afferent information regarding movement and balance arising 588
from the mesencephalon, the brainstem, and the spinal cord enters the cerebellum via the cerebellar peduncles, 589
and regulation of movement is coordinated by the inhibitory influence of Purkinje neurons on the cerebellar nuclei. Information enters the cerebellum via the cerebellar peduncles and is carried on two major afferent nerves termed *mossy fibers* and *climbing fibers*.[1] Mossy fibers originate from the brainstem and spinal cord. Mossy fibers send collateral fibers to synapse with the cerebellar nuclei; they terminate by synapsing with granule neurons in the cerebellar cortex. These fibers are facilitory at these synapses. The axons that granule neurons send to the molecular layer course transversely through this layer to synapse with the dendritic zone of multiple Purkinje cells and also provide facilitory influence at these synapses. Climbing fibers originate in the olivary nucleus, which provides most of the extrapyramidal projections to the cerebellum. Similar to mossy fibers, climbing fibers send collaterals to synapse on neurons in the cerebellar nuclei; however, the axon continues through the cerebellar cortex to synapse with the dendritic zone of the Purkinje neurons in the molecular layer. As with mossy fibers, climbing fibers provide a facilitative influence at the synapses.

Figure 10.7-1 Schematic diagram of cerebellar efferent and afferent information pathways via the cerebellar peduncles. The arrow size reflects the relative contribution of each pathway. See text for details.

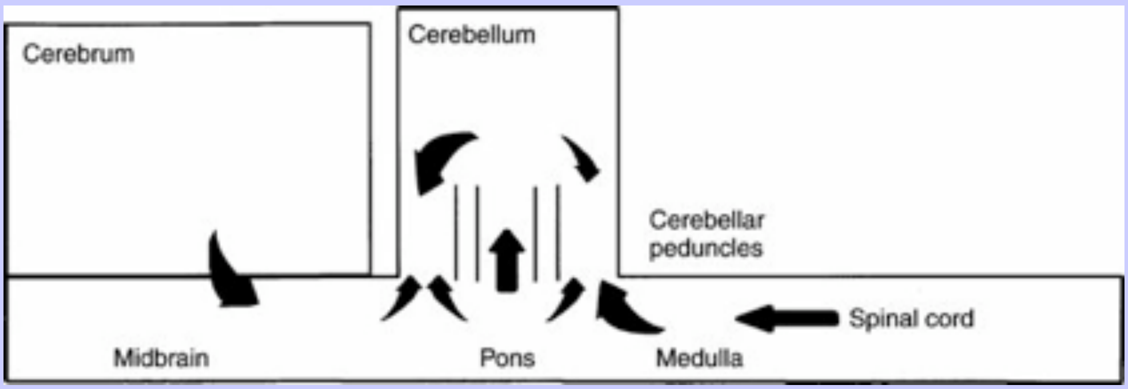

Figure 10.7-2 Photomicrograph of a normal cerebellum.*M,* Molecular layer; *P,* Purkinje layer; *G,* granular layer; *Md,* medulla; *arrowhead,* a Purkinje neuron. (Hematoxylin-eosin stain, ×55.) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, Wash.)

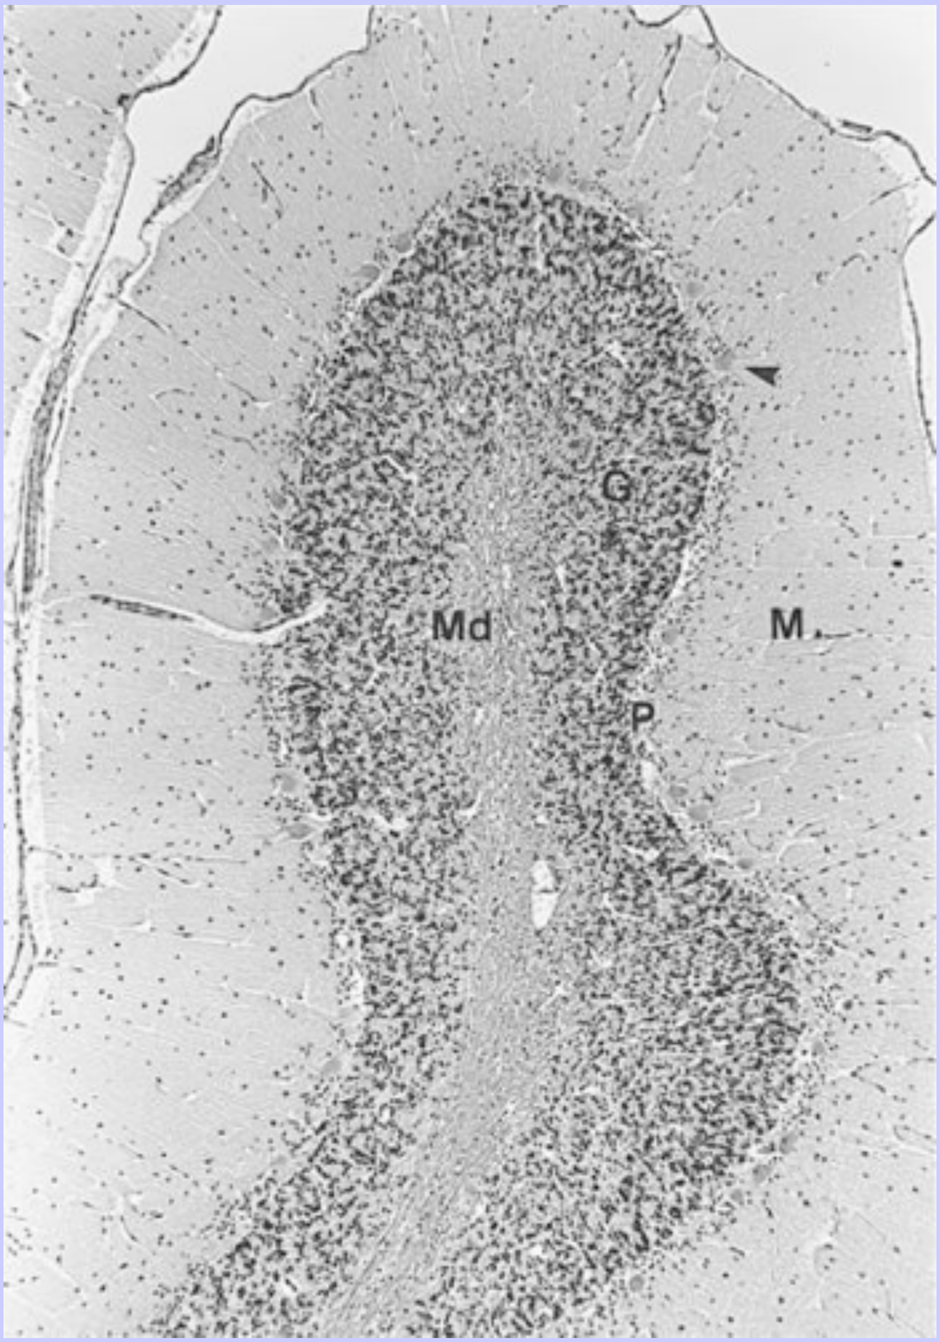


Purkinje neurons provide the sole efferent fibers from the cerebellar cortex. The majority of Purkinje cell axons terminate on neurons in the cerebellar nuclei, although direct projections from these neurons to the vestibular nuclei occur via the caudal cerebellar peduncle. Purkinje neurons are inhibitory and use the neurotransmitter γ-aminobutyric acid.[1] Efferent nerves from the cerebellum are primarily from the cerebellar nuclei that facilitate activity of upper motor neurons originating in the brainstem.

Thus much of the influence of the cerebellum on skeletal muscle activity is to modulate the upper motor neuron. Information regarding movement and balance enters the cerebellar cortex via the cerebellar peduncles. This 589
afferent activity stimulates inhibitory Purkinje neurons by climbing or mossy fibers. Purkinje neurons in turn 590
modulate the activity of the cerebellar nuclei to regulate movement and muscular tone. Purkinje neurons also provide direct inhibitory input to the vestibular nuclei.

10.7.2 Clinical Signs

Clinical signs associated with cerebellar disease generally reflect the loss of coordination. Mentation is normal in horses with cerebellar disease, provided that other regions of the brain are unaffected and metabolic disturbances such as septicemia or endotoxemia are not present. Cerebellar disturbances result in ataxia and inability to regulate the rate, range, and force of movement.[1] Dysmetria refers to alterations in the range of gait. Hypermetria is an exaggerated range of movement. When moving, the limb has a higher or longer flight compared with normal. Hypometria is a diminished movement; for example, the arc of flight of a limb in motion may be lower. Horses showing hypometria tend to hit objects with the limb when stepping over them and may fail to extend the limb far enough to set the foot down on a step. Initiation of movement may be jerky and awkward, and the trunk may sway from side to side when the horse moves. Spasticity is caused by hypertonia and results in a jerky stiff gait. Paresis is not a feature of cerebellar disease because the cerebellum does not initiate voluntary motion, although a horse that is unable to regulate rate and range of motion sometimes may appear weak and drag its toes. Diffuse cerebellar disease results in bilateral signs. In general, unilateral lesions result in signs ipsilateral to the lesion.

Intention tremor is another prominent sign of diffuse severe cerebellar disease. Tremor is most obvious as vertical or horizontal head motions and can be observed readily as a horse approaches feed or attempts to nurse. The tremor is present only when a movement is initiated and tends to become more exaggerated as the horse approaches an object.

Cerebellar disease also may cause loss of the blink reflex and vestibular abnormalities. The horse may fail to blink in response to an ocular menace. The exact mechanism for this deficiency is unknown; however, a portion of the visual pathway from the visual cortex to the facial nucleus (which initiates the blink) likely travels through the cerebellum. Disruption of the flocculonodular lobe, located in the ventral cerebellum, or the fastigial nucleus may result in vestibular signs characterized by disequilibrium; a variable nystagmus, which may be positional; and positioning difficulties.[1] Unilateral lesions may result in a head and body tilt toward the side of the lesion and nystagmus with the fast phase away from the lesion. Paradoxical vestibular syndrome characterized by a head tilt away from the lesion and nystagmus with the fast phase toward the lesion is apparent with unilateral lesions involving the cerebellar peduncle.[1,2]

10.7.3 Diseases of the Cerebellum

10.7.3.1 CEREBELLAR ABIOTROPHY AND DEGENERATION

Cerebellar abiotrophy is the most commonly reported cerebellar disease in horses.[3–10] Abiotrophy in the nervous system refers to premature degeneration of neurons caused by some intrinsic abnormality in their structure or metabolism.[11] Cerebellar abiotrophy has been reported in Arabian, Gotland pony, and Oldenburg horse breeds. Degenerative cerebellar lesions have been observed in one Thoroughbred and two Paso Fino newborn foals.[12] Arabian and part-Arabian horses in North America are affected most frequently.[3–6,8–10] The incidence in some Arabian horse herds has been reported to be as high as 8%. In one report, colts were affected more frequently than fillies, although subsequent reports have not substantiated this finding.[5] The cerebellar abiotrophy that occurs in Oldenburg horses is progressive and fatal with atypical histologic lesions compared with the syndrome that occurs in Arabian foals.[13]

Cerebellar abiotrophy generally affects foals less than 1 year of age and occurs most frequently in 1- to 6-month-old foals. Adult-onset cerebellar abiotrophy has been reported in other species such as the dog and has been observed in two equine cases.[1] Many foals are born with no abnormalities and later develop disease; however, occasionally they are affected at or shortly following birth.[5,6,9]

Clinical signs associated with cerebellar abiotrophy include intentional head tremor, ataxia, wide-based stance and gait, dysmetria, and spasticity.[3–10] The most frequently reported initial signs noted by owners are an intentional head tremor, vertical or horizontal, or a hypermetric forelimb gait.[3,9] The neurologic examination reveals no change in mentation. One almost never observes nystagmus, which has been reported in only one case of abiotrophy in a Gotland pony.[7] A menace reflex frequently is absent or diminished.[6,9] One must interpret this finding with caution because normal foals may lack or have a depressed menace reflex until at least 2 weeks of age.[14]

Stance and gait abnormalities seen with cerebellar abiotrophy generally consist of a wide-based stance or gait and ataxia.[6,8,9] The foal may move stiffly and have a high goose-stepping gait. The horse may protract the limb when walking, resulting in slamming of the foot to the ground. Movement may be spastic with circumduction. Walking on an incline, asking the foal to step over obstacles, and blindfolding the foal exacerbate gait abnormalities. Generally, gait abnormalities are symmetric, although in a Welsh Cob–Arabian- 590
cross foal the initial signs were characterized by a stiff motion in the left front limb. Signs in this foal 591
progressed to severe ataxia.[4] Foals affected at birth may have difficulty rising.[5–7] Despite this finding, weakness is not a feature of the clinical signs associated with cerebellar abiotrophy. Spinal reflexes are usually normal. Some affected animals fall when startled or when raising the head. Signs are generally progressive for several months following diagnosis. Once the animal has reached maturity, the condition becomes static, although mild improvement has been observed.[10]

Ancillary testing is of limited value in diagnosing cerebellar abiotrophy but can be helpful to rule out other causes of ataxia. The complete blood count and serum biochemistry profile are normal in affected foals. Abnormalities in cerebrospinal fluid (CSF) are detectable. In one study, three of four foals had an elevated CSF creatine kinase activity. Values in affected foals ranged from 6.6 to 62 IU/μL (normal range, 0 to 8 IU/

µL).[9] CSF creatine kinase elevations generally are associated with neural necrosis or degeneration, although they are not associated specifically with a particular disease.[15–17]

In addition, CSF total protein may be elevated. In the study cited previously, three foals had elevated total protein with an average of 226 mg/dl (normal, 0 to 100 mg/dl) in all foals with cerebellar abiotrophy. As with creatine kinase, total protein elevations are not specific for abiotrophy and may occur with disruption of the blood-brain barrier or with central nervous system inflammation or degeneration. Many foals with cerebellar abiotrophy have normal CSF analysis. Electroencephalographic abnormalities, including increased synchrony and increased number of abrupt frequency changes, also may be detectable in affected foals.[9] In this study, these abnormalities were not observed in normal foals anesthetized under similar conditions. Skull and cervical radiographs are unremarkable. However, because mentation is normal in foals with cerebellar abiotrophy, electroencephalographic examination is not necessary to make a diagnosis and is primarily useful to exclude seizure disorders as a cause of the tremors observed.

Antemortem diagnosis of cerebellar abiotrophy is based on a typical history and the clinical signs of intention tremor, lack of menace, and failure to blink to bright light, and ataxia in Arabian or part-Arabian foals or Gotland pony foals. The differential diagnoses for cerebellar abiotrophy include cranial malformations; congenital spinal malformations, including atlantoaxial malformations and stenotic myelopathy; inflammation or infection of the cerebellum; and trauma. One can rule out these conditions based on the neurologic examination, CSF analysis, and radiography. The signs of characteristic ataxia and head tremor without weakness in the appropriate breed is nearly pathognomonic.

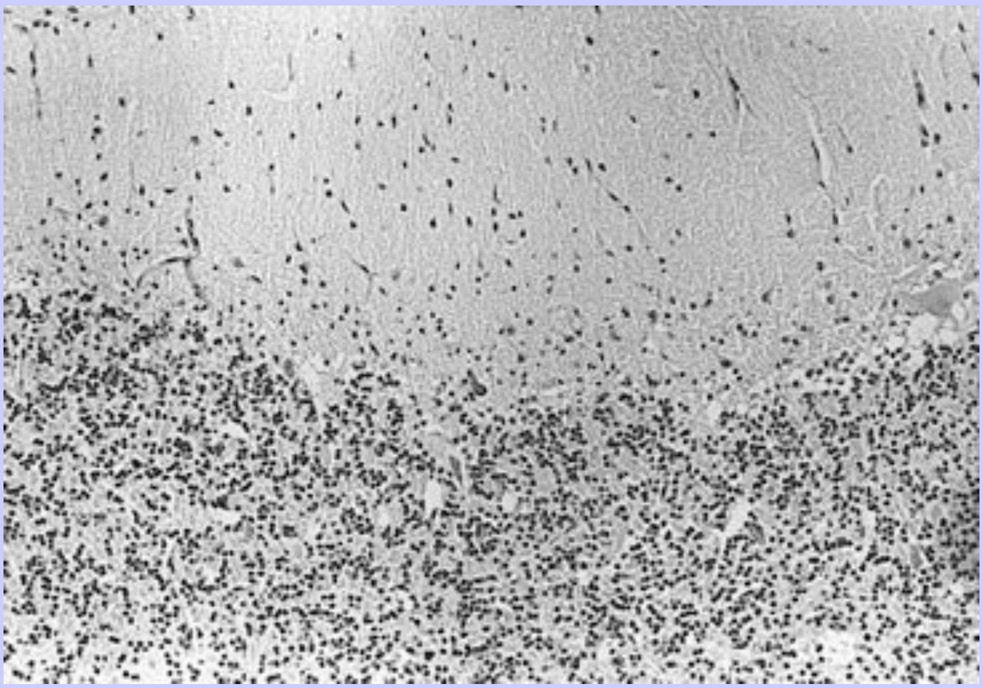
Postmortem examination provides a definitive diagnosis of this disorder. Generally, no gross abnormalities are notable; however, careful examination of the cerebellum may reveal an increased lobular pattern with prominent folia. In the Gotland pony, the weight ratio of the cerebellum to the cerebrum is reduced significantly in foals with cerebellar abiotrophy.[7] Normal foals had a 13% ratio, and affected foals had a 10% ratio. In the degenerative cerebellar condition in the Paso Fino and Thoroughbred foals, a decrease in the cerebellar-to-whole brain weight ratio was evident.[12] This ratio in normal foals was 8% and in affected foals was 6%.

Histologic abnormalities are consistent in cases of cerebellar abiotrophy. The most prominent finding is the widespread loss of Purkinje neurons[3–10] (Figure 10.7-3). Degenerative changes, such as shrunken and angular neurons with hyperchromasia and dispersion of Nissl's substance, are apparent. One may observe occasional “baskets” or clear spaces where the Purkinje neuron is lost. Thinning of the molecular layer occurs with gliosis. The granular layer is also thin with a loss of cellularity. Similar histologic findings were found in Thoroughbred and Paso Fino foals with vacuolation and proliferation of Bergmann's glia in the Purkinje cell layer.[12]

The pathogenesis of cerebellar abiotrophy is unknown. Viral, toxic, and genetic causes have been suggested.[3,5,6,9] To date no evidence has been found to support an infectious cause. No virus has been isolated from the CSF or brain of affected foals, and no viral inclusions have been observed on histologic examination. No toxin 591
has been associated consistently with cerebellar abiotrophy of Arabian foals. A genetic cause may be present. 592
Pedigree analysis of affected Arabian foals has shown a high degree of inbreeding of affected foals, although this breed is generally inbred.[5] Interestingly, in this study three of six foals from one mare suffered from cerebellar ataxia; all affected foals had different sires. A similar pedigree analysis was performed in the Gotland pony in which an autosomal recessive mode of inheritance was suggested.[7] Similar to Arabian foals, a high degree of inbreeding was noted, making a highly significant conclusion difficult. Attempts to breed

affected individuals in this study were unsuccessful. Although a definitive mode of inheritance has not been demonstrated in either breed, a familial tendency is suggested.

Figure 10.7-3 Photomicrograph of the cerebellum from a 9-month-old foal with cerebellar abiotrophy. The decreased number of Purkinje neurons is notable. (Hematoxylin-eosin stain, ×139.) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, Wash.)



No treatment exists for cerebellar abiotrophy. As noted previously, signs may be progressive until the foal reaches maturity. Signs may stabilize or improve slightly with time.

10.7.3.2 GOMEN DISEASE

Gomen disease is a degenerative cerebellar condition recognized in the northwest part of New Caledonia.[18] Gomen disease is a progressive cerebellar disease that causes mild to severe ataxia. Horses that are indigenous or are introduced to the region may be affected. The disease occurs only in horses that are allowed to roam free, and signs may take 1 to 2 years to develop once a horse is introduced into an endemic area. Horses that are confined generally are unaffected. Clinical signs consist of ataxia, which is most prominent in the hindlimbs; toe dragging; and a wide-based stance. As the disease progresses, weakness becomes prominent and horses may have difficulty rising. The signs are primarily referable to involvement of the cerebellum; however, weakness likely is caused by brainstem or spinal cord involvement. Nystagmus is not observed. Ataxia is progressive over 3 to 4 years until the horse dies or is euthanized.

Mild cerebellar atrophy may be apparent on gross examination of the brain. Histologically, severe depletion of Purkinje neurons is evident throughout the cerebellum.[19] Purkinje neurons may contain lipofuscin pigment and vacuoles. One horse examined had moderate loss of granule cells. Moderate to severe lipofuscin pigmentation of neuron cell bodies occurs throughout the brain and spinal cord. Although lipofuscin accumulation may be considered a normal variation of aging, the degree of pigment accumulation is far more severe than that in horses of similar age.

The pathogenesis of this disease is unknown. Pedigree analysis has not revealed any genetic component for susceptibility to development of disease.[18] A condition of neuronal lipofuscinosis in dogs has some similarities to this disease.[19] The accumulation of lipofuscin pigment and association with free-ranging horses suggests a metabolic disorder, perhaps resulting from toxicity.[18,19]

10.7.3.3 DEVELOPMENTAL ABNORMALITIES

Dandy-Walker syndrome is characterized by a midline defect of the cerebellum and cystic dilation of the fourth ventricle, which separates the cerebral hemispheres.[20] Frequently, all or portions of the cerebellar vermis fail to form, and the corpus callosum may be absent. The condition is rare in horses and has been observed in Thoroughbred and Arabian foals.[21,22] Foals with this syndrome may be abnormal neurologically from birth, with difficulty rising, seizures, and absence of the suckle reflex.[21] The forehead may be domed excessively. Ataxia, nystagmus, aggression, and difficulty in training may persist as the foal ages.[21,22] Diagnosis generally is made at postmortem examination; however, one case was diagnosed antemortem using computed tomography.[21]

Several individual cases of equine developmental cerebellar abnormalities have been described. Cerebellar hypoplasia has been described in a Thoroughbred foal that had difficulty rising and developed seizures shortly after birth.[23] This report did not describe the histologic findings of cerebellar hypoplasia in detail; thus the relationship between this finding and cerebellar abiotrophy or degeneration in Arabian foals is unknown. Bilateral focal cerebellar cortical hypoplasia has been reported in a 6-year-old Thoroughbred gelding.[24] No gait abnormalities were detected in this horse, although it had fallen over repeatedly before euthanasia. The relationship between falling and the cerebellar abnormality is unclear. Possibly the abnormality in this adult horse resulted from a secondary problem, such as vascular injury, rather than a developmental defect.[13]

A single case of cerebellar dysplasia has been described in a 4-year-old Thoroughbred horse.[25] This horse had a 7-month history of circling and collapsing to the left side. In this case the horse had hyperplasia of the right side of the cerebellum with no associated central white matter. Histologically, the granule layer was thinning, with increased thickness of the molecular layer and cavitation of the white matter.

Additional reported developmental disorders include cerebellar hypoplasia with internal hydrocephalus and cerebellar aplasia with hydranencephaly in two fetuses from Haflinger mares with hydrops allantois.[26] Mild cerebellar degenerative changes consisting of Purkinje neuron granularity has been noted in a Standardbred filly with a chromosomal abnormality.[27] This abnormality was accompanied by mild spongiotic degeneration of the cerebrum. Abnormal neurologic signs in this filly included difficulty standing at birth, mental dullness, 592
and a head tilt. These signs were accompanied by growth retardation, small inactive ovaries, and a consistently 593
wrinkled muzzle.

10.7.3.4

INFECTIOUS CONDITIONS

Unlike in many other large animals, no infectious agents have the cerebellum as their primary target; however, a number of agents may affect the cerebellum. Any agent that targets the central nervous system, especially those that have a multifocal distribution, also may involve the cerebellum.

Equine protozoal myelitis is a protozoal disease caused by *Sarcocystis neurona*. This agent causes multifocal inflammation and necrosis of the central nervous system. The most common signs associated with *S. neurona* infection are spinal ataxia, weakness, and muscle atrophy, although this agent also can affect the cerebellum. Clinical signs associated with cerebellar involvement may reflect diffuse or focal involvement. A head tilt or asymmetric ataxia without weakness or lower motor neuron signs may be associated with focal disease. Diagnosis is based on multifocal neurologic disease and the presence of antibody to *S. neurona* in the CSF. Additional information regarding this disease may be found in Chapter 10.10.

Equine herpesvirus type 1 causes multifocal meningoencephalitis resulting from vasculitis, vascular thrombosis, and ischemia of nervous tissue. Although the primary signs associated with this agent include spinal ataxia, cranial nerve abnormalities, and signs associated with involvement of the cauda equina, this agent also may affect the cerebellum. As with equine protozoal myelitis, involvement may be focal, multifocal, or diffuse.

Occasionally, disseminated *Streptococcus equi* infection (bastard strangles) may result in a cerebellar abscess.[28] Neurologic abnormalities in one reported case included proprioceptive deficits in the right forelimb, nystagmus, and a head tilt. Meningitis contributed to other central nervous signs such as depression, blindness, and recumbency. Diagnosis of this condition can be based on a history of previous *S. equi* infection, evidence of severe suppurative inflammation in the CSF, and culture of *S. equi* from the CSF. Treatment consists of penicillin. The prognosis is guarded; however, successful surgical drainage of a cerebral *S. equi* abscess has been reported.[29]

Focal involvement of the cerebellum has been associated with aberrant parasite migration in the horse.[4,30] In a 6-year-old pony, infection with *Halicephalobus deletrix* resulted in severe ataxia.[30] Histologic study showed lesions scattered throughout the cerebellum, brainstem, thalamus, and pituitary gland, and nematodes were observed throughout the lesions. A second case involving a 1-year-old Thoroughbred colt had a sudden onset of severe ataxia.[4] Multifocal malacia with numerous eosinophils was observed throughout the cerebellar white matter. No nematode was detected, although parasitic involvement was suspected based on the eosinophilic inflammation.

10.7.3.5

MISCELLANEOUS CONDITIONS

A familial neurologic condition in newborn Thoroughbred foals has been reported.[31] This syndrome affected three of five foals of a Thoroughbred mare. The foals were normal at birth and developed signs of severe incoordination, a wide-based stance, and recumbency at 2 to 5 days of age. The condition appeared more severe when the foals became excited or struggled; consequently, they were treated symptomatically with diazepam. The signs would improve with this treatment and return as the sedation wore off. These foals improved with stall rest over 7 to 10 days. The cause of the clinical signs in these foals is unknown; however, the authors suggested possible viral or toxic causes.

Cerebellar ataxia in two Thoroughbred fillies has been associated with hematoma in the fourth ventricle.[32] These two horses demonstrated fever, dysmetria, spasticity, and weakness. Clinical signs most likely resulted from compression of the adjacent cerebellum. CSF analyses in these cases revealed xanthochromia, elevated red and white blood cell counts, and elevated total protein concentrations. The cause of the hematomas was not identified; damage to regional small vessels and a vascular anomaly were suspected.

Chronic methylmercurial poisoning in horses can cause a number of clinical abnormalities, including cerebellar ataxia.[33] Severe poisoning can result in incoordination, dysmetria, and gross head nodding in the experimental setting. Associated clinical signs include lethargy, anorexia, exudative dermatitis, and laminitis. Lesions in the cerebellum consisted of focal atrophy and cellular depletion in the granular layer with little to no involvement of Purkinje cells. Additional abnormalities included neuronal necrosis and gliosis in the cerebrum, lymphocytic perivascular cuffing, and swollen axons in the spinal cord. Preferential accumulation of inorganic mercury in the brain and resulting cell injury most likely led to the neurologic signs observed. Diagnosis of methylmercurial poisoning can be based on clinical signs and measurement of mercury in the liver and kidney (see Chapter 20).

10.8

10.8—Cervical Vertebral Stenotic Myelopathy

Randolph H. Stewart

Bonnie R. Rush

593

Cervical stenotic myelopathy (CSM) is a developmental disease of the cervical vertebrae characterized by stenosis of the cervical vertebral canal resulting in intermittent or continuous compression of the spinal cord.[1–3] Clinically the disease is characterized by weakness, ataxia, and spasticity of all limbs. Two general manifestations of this syndrome are cervical vertebral instability (CVI) and cervical static stenosis (CSS).[1,2] CVI is a dynamic condition in which spinal cord compression is intermittent and occurs when the cervical vertebrae are in the ventroflexed position.[4,5] The intervertebral sites most commonly involved in horses with CVI are C3 to C4 and C4 to C5.[6,7] In horses with CSS, spinal cord compression is continuous regardless of cervical position and occurs predominantly in the caudal cervical region: C5 to C6 and C6 to C7.[2,7] 594

CSM occurs most frequently in rapidly growing, young male horses.[4,8–10] Although CSM has been reported in most light and Draft breeds and in both sexes, it occurs more commonly in Thoroughbreds and Quarter Horses.[2,4,5,9] Early reports of CSM suggested that cranial and middle cervical lesions occurred in young horses (6 to 30 months) and caudal lesions in older horses (>5 years).[5] Subsequent studies, however, have not supported this observation. A retrospective study of 306 myelograms involving mostly Thoroughbreds reported 1- to 2-year-old horses to be affected most frequently and showed C3 to C4 to be the most commonly affected intervertebral site. In 594
most instances, no difference in site distribution of lesions exists between horses less than or equal to 2 years of age 595
and those greater than 2 years of age.[7]

10.8.1 Clinical Signs

Cervical vertebral stenotic myelopathy is characterized by symmetric ataxia, paresis, and spasticity, which are usually worse in the pelvic limbs than thoracic limbs.[4,9,10] At rest, affected horses often assume a wide-based stance and demonstrate delayed responses to proprioceptive positioning. Stumbling, toe dragging, circumduction of the hindlimbs, and truncal sway are often observable at a walk. These signs are accentuated by manipulation during neurologic examination using circles, hills, obstacles, and elevation of the head.[4,5,9] The laryngeal adductor response test may be abnormal. Clinical signs of ataxia often progress for a short period of time and then stabilize.[4,5] A history of a traumatic incident often is associated with the onset of CSM; however, ataxia was likely present before the traumatic incident. In many cases the fall results from mild neurologic deficits, and the traumatic incident exacerbates the stenosis leading to trauma of the spinal cord and resultant clinical signs of spinal cord compression.

Infrequently, evidence exists of gray matter and spinal nerve root damage such as cervical pain, atrophy of the cervical musculature, or cutaneous hypalgesia adjacent to the affected cervical vertebrae.[8,9,11] These signs are observed more commonly in horses over 4 years of age with significant arthropathy of the caudal cervical vertebrae (C5 to C7).

Clinical signs of concurrent developmental orthopedic disease of the appendicular skeleton, such as physeal enlargement of the long bones, joint effusion following osteochondrosis, and flexural limb deformities, are often present in young horses with CSM.[4,5,12] In addition, affected horses may have another concurrent neurologic disease such as equine protozoal encephalomyelitis.

10.8.2 Pathogenesis and Pathologic Findings

One of the most consistent pathologic changes observed in horses with CSM is narrowing of the vertebral canal as evidenced by decreased minimum sagittal diameter (MSD).[8,11,13,14] One can determine the MSD for each cervical vertebra by taking the smallest sagittal diameter of the vertebral canal via radiographic or postmortem examination.[8] Horses affected with CSM have a narrowed MSD at C3 to C6, regardless of the site of spinal cord compression.[8,11,13,14] In cases of CSS, narrowing of the canal diameter is exacerbated by thickening of the dorsal lamina, enlargement of the ligamentum flavum, and degenerative articular processes with thickened joint capsules.[2,12] Abnormalities of the dorsal lamina and ligamentum flavum are not observed in young Thoroughbreds affected by CSM[13] and appear to be more common in the older horses affected with CSM.[2] In some cases of CSS, flexion of the neck stretches the thickened ligamentum flavum and relieves spinal cord compression, whereas hyperextension exacerbates compression.[6,8] Pathologic changes of the cervical vertebrae most commonly observed in horses with CVI are instability and subluxation of adjacent vertebrae, malformation of the caudal vertebral physis or epiphysis (caudal epiphyseal flare), and malformation or malarticulation of the articular processes.[1,8] Histopathologic examination of the spinal cord reveals wallerian degeneration, malacia, and fibrosis at the sites of spinal cord compression and demyelination in the ascending and descending white matter tracts within adjacent segments of the spinal cord proximal and distal to the site of spinal cord compression.[8,9]

Many studies have identified an association between CSM and developmental orthopedic disease in horses, although no causal relationship has been established.[1,2,12,13,27] Osteochondrotic lesions are more severe in the articular processes of the cervical vertebrae and are more frequent and severe in the appendicular skeleton in horses affected with CSM than in clinically normal horses.[13] Instability between adjacent vertebrae, caused by osteochondrosis and subsequent degenerative joint disease of the articular processes, may lead to generation of excessive or inappropriate biomechanical forces on the ligamentum flavum, joint capsule, and dorsal lamina.[2] Thickening and fibrosis of these structures contribute to narrowing of the vertebral canal in horses with CSS. Osteochondrosis of the articular processes is not always present at the site of spinal cord compression in horses with CVI.[8,13] Physeal osteochondrosis may produce caudal epiphyseal malformation and vertebral instability in cases of spinal cord compression in which osteochondrosis of the articular processes is not present. Conversely, CSM and osteochondrosis may be two separate manifestations of developmental orthopedic disease characterized by an underlying inability to form normal cartilage and bone, and the occurrence of CSM may result from generalized failure of vertebral canal development rather than from osteochondrosis.[13] Nonetheless, the association between osteochondrosis and CSM indicates that the cause and pathophysiology of these two conditions are similar.

The cause of CSM appears to be multifactorial, involving genetic and environmental influences. No evidence indicates that CSM is directly heritable by simple mendelian dominant or recessive patterns.[15] Rather the mode of inheritance may involve multiple alleles and variable penetrance determining a genetic predisposition to CSM. Nutrition, rapid growth, trauma, and abnormal biomechanical forces likely contribute to the development of CSM in genetically predisposed individuals.[1,16–19] 595

596

Dietary factors investigated in the pathogenesis of osteochondrosis and CSM include dietary copper, zinc, protein, and carbohydrates. Low dietary copper and high zinc concentrations produce severe osteochondrotic lesions in foals.[20,21] Additionally, diets containing 15 ppm copper produce 3 times as many osteochondrotic

lesions of the appendicular and axial skeleton compared with diets containing 55 ppm copper.[16–18,22–24] Correction of trace mineral balance including zinc, calcium, and phosphorus, along with copper supplementation, decreases the incidence of developmental orthopedic disease in foals.[16,17,22] Copper supplementation does not eliminate developmental orthopedic disease completely, suggesting other etiologic factors must exist. Excessive carbohydrates in the diet are hypothesized to contribute to the pathogenesis of osteochondrosis through endocrine imbalance.[19,25–28] A high-carbohydrate meal (130% of the National Research Council [NRC] recommendation) results in postprandial elevation of serum insulin concentration and depression of serum thyroxine concentration.[25] Insulin stimulates the zone of chondrocyte proliferation, and thyroxine stimulates the zone of chondrocyte maturation at the growth plate.[27,28] High insulin and low thyroxine concentrations are suspected to promote cartilage proliferation and retention without promoting maturation. Cartilage retention and failure of maturation are consistent with the histopathologic appearance of osteochondrosis. Endocrine alterations associated with a high-carbohydrate diet are the basis for the “paced diet” program for prevention and treatment of CSM.[29,30] A correlation between dietary protein concentrations and the incidence of osteochondrosis and CSM has not been identified.[16–18]

10.8.3 Diagnosis

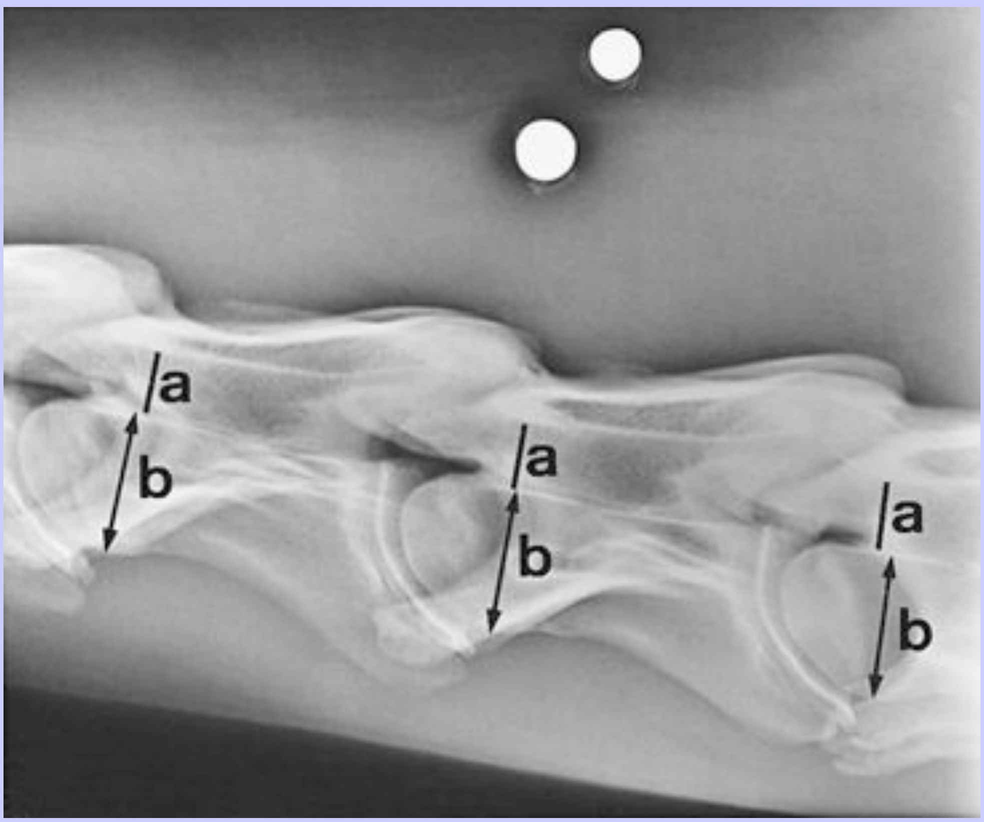
The differential diagnosis of CSM includes neurologic diseases that produce tetraparesis and incoordination, such as equine herpesvirus type 1 myeloencephalitis, equine protozoal myeloencephalitis, equine degenerative myeloencephalopathy, occipitoatlantoaxial malformation, spinal cord trauma, vertebral fracture or luxation, vertebral abscessation, and verminous myelitis.[4] Neurologic examination, cerebrospinal fluid analysis, and radiographic procedures are indicated in horses with symmetric tetraparesis and ataxia.[31]

One should examine lateral radiographic views of the cervical vertebrae to obtain objective determination of vertebral canal diameter and subjective assessment of vertebral malformation. Characteristic malformations of the cervical vertebrae in horses with CSM include flare of the caudal epiphysis of the vertebral body, abnormal ossification patterns of the articular processes, subluxation between adjacent vertebrae, extension of the dorsal laminae, and degenerative joint disease of the articular processes.[29,30] Degenerative joint disease of the articular processes is the most frequent and severe malformation observed in horses with CSM.[14] However, degenerative joint disease of the articular processes occurs in 10% to 50% of nonataxic horses,[8,14,32] and subjective evaluation of degenerative joint disease of the articular processes in the caudal cervical spine results in the false-positive diagnosis of CSM.[7] Although the presence of characteristic vertebral malformations supports the diagnosis of CSM, subjective evaluation of bony malformation from radiographs of the cervical vertebrae does not reliably discriminate between horses affected and unaffected by CSM.[7,14]

Objective assessment of the vertebral canal diameter is more accurate than subjective evaluation of bony malformation for identification of horses with CSM. The most reliable objective determination of vertebral canal diameter from standing radiographs of the cervical vertebrae is the sagittal ratio technique. One calculates the sagittal ratio by dividing the MSD by the width of the vertebral body.[14] One measures the vertebral body width perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body (Figure 10.8-1). This technique eliminates variability in absolute MSD values because of magnification. The vertebral body is located within the same anatomic plane as the vertebral canal; therefore the proportion of these two objects will be the same regardless of the degree of radiographic magnification.[33] The sagittal ratio technique has a sensitivity and specificity equal to or greater than 89% for vertebral sites C4 to C7 and should be used to 596 597

determine the likelihood of the presence of CSM in an individual with spinal ataxia.[14] If the sagittal ratio at a particular vertebral site is below the reference value for that site, one should perform myelographic examination to confirm the diagnosis of CSM. If the sagittal ratio is greater than the reference value, one should avoid or postpone myelographic examination until after performing diagnostic tests focused on alternative causes of spinal ataxia. The reference values for sagittal ratio measurements of the cervical vertebrae are 52% at C4 to C6 and 56% at C7. Accurate measurement of the sagittal ratio value requires a precise, lateral radiograph of the cervical vertebrae. Obliquity of the cervical vertebrae results in indistinct margins of the ventral aspect of the vertebral canal, producing erroneous values for MSD and vertebral body width.

Figure 10.8-1 Lateral radiographic view of the fourth, fifth, and sixth cervical vertebrae. One determines the sagittal ratio at each vertebral site by dividing the minimum sagittal diameter *(a)* by the width of the cranial aspect of the vertebral body *(b)* at its widest point.



A semiquantitative scoring system for assessing cervical radiographs has been developed to identify CSM in Thoroughbred foals up to 1 year of age.[29,30,34] The semiquantitative scoring system incorporates objective determination of vertebral canal stenosis and subjective evaluation of vertebral malformation. The maximum total score is 35 points, and a total score of 12 or higher constitutes a radiographic diagnosis of CSM. One assesses stenosis of the vertebral canal by determining the inter- and intravertebral MSD; the maximum score

designated for vertebral canal stenosis is 10 points. One corrects the inter- and intravertebral MSDs for radiographic magnification by dividing the MSD by the length of the vertebral body. One then determines malformation of the cervical vertebrae by subjective assessment of each of the following five categories: (1) enlargement of the caudal physis of the vertebral body, (2) caudal extension of the dorsal lamina, (3) angulation between adjacent vertebrae, (4) delayed ossification of bone, and (5) degenerative joint disease of the articular process. The maximum score allotted for each category of bony malformation is 5 points. This semiquantitative scoring system is a noninvasive method for predicting and diagnosing the presence of CSM in Thoroughbred foals up to 1 year of age.[34]

Myelographic examination is required for definitive diagnosis of CSM.[6,35] Use of the sagittal ratio method for determining specific sites of spinal cord compression overestimates the number of sites of spinal cord compression within the CSM-affected population.[8,11,13] In addition, subjective evaluation of bony malformation results in inaccurate diagnosis of the sites of spinal cord compression. The severity of vertebral abnormalities does not necessarily correspond to the site of spinal cord compression, and spinal cord compression can occur from stenosis of the vertebral canal at vertebral sites that lack bony malformation.[7,8,13] Therefore radiographs of the cervical vertebrae cannot replace myelographic examination for identification of the location, number of affected sites, and classification of spinal cord compressive lesions in horses with CSM.[31]

Definitive diagnosis of CSM is determined by 50% or greater decrease in the sagittal diameter of the dorsal and ventral dye columns at diametrically opposed sites.[6,35] This decrease is quantified by comparing it with the midvertebral site cranial or caudal to the compressed site. The ventral column often is obliterated totally at the intervertebral sites in normal studies, particularly in the flexed position; therefore a 50% or greater decrease in opposing dorsal and ventral columns must be present for diagnosis of CSM. In horses with obvious sites of spinal cord compression identified on myelographic views with the cervical vertebrae in the neutral position, one should avoid excessive manipulation of the neck so as to obtain flexed and extended myelographic views to prevent exacerbation of spinal cord injury.

Although myelographic examination has been shown to be a safe procedure,[6,7] it is not without risk. The contrast agent metrizamide may produce depression, increased ataxia, fever, seizures, meningitis, and muscle fasciculations.[36–38] Nonionic, water-soluble contrast agents such as iopamidol and iohexol provide superior radiographic contrast with fewer adverse effects than metrizamide.[35,39] Regardless of the contrast agent used, one should reserve myelographic examination for those cases in which the risk and the cost are justified. Indications for myelographic examination include confirmation of a definitive diagnosis of CSM at the owner's request, insurance purposes, before euthanasia, and identification of the exact site(s) of spinal cord compression before surgical intervention.

Analysis of cerebrospinal fluid shows the fluid often is within reference ranges in horses with CSM.[4,9,31] In instances in which cerebrospinal fluid is abnormal in horses with CSM, the alterations are consistent with acute spinal cord compression, such as mild xanthochromia or mild increases in protein concentrations.[9]

10.8.4 Treatment

Surgical intervention is the most widely reported treatment for CSM.[40–46] Stall rest, glucocorticoids, dimethyl sulfoxide, and other antiinflammatory drugs may provide transient improvement in clinical signs, but effective treatment must be directed at preventing further spinal cord injury.[5] The goals of surgical intervention in horses with CSM are stabilization of the cervical vertebrae and decompression of the spinal cord. Cervical vertebral

interbody fusion provides intervertebral stability for horses with dynamic spinal cord compression (CVI). Affected cervical vertebrae are fused in the extended position to provide immediate relief of spinal cord compression and prevent repetitive spinal cord trauma.[41,42,44,45]

597
598

One achieves immediate decompression of the spinal cord in cases of CSS by subtotal dorsal laminectomy in which one removes portions of the dorsal lamina, ligamentum flavum, and joint capsule overlying the compressed site.[5,43,47,48] This procedure effectively decompresses the spinal cord but is associated with significant postoperative risk.[42] Interbody fusion of caudal cervical vertebrae in horses with CSS produces remodeling and atrophy of the articular processes, resulting in delayed decompression of the spinal cord over a period of weeks to months.[40,41] Decompression is immediate with dorsal laminectomy; however, because of its safety, interbody fusion is selected by some surgeons as the technique of choice for CSS and CVI.[42]

Cervical vertebral interbody fusion results in improvement in neurologic status in 44% to 90% of horses with CVI and CSS, and 12% to 62% of horses return to athletic function.[5,41,42,44,46] Subtotal dorsal laminectomy results in improvement in neurologic status in 40% to 75% of horses with CSS.[42,43] Subtotal dorsal laminectomy and cervical vertebral interbody fusion for CSS of the caudal cervical vertebrae are associated with fatal postoperative complications, including vertebral body fracture, spinal cord edema, and implant failure. The most important patient factor for determination of postoperative prognosis is duration of clinical signs before surgical intervention; horses with clinical signs for less than 1 month before surgery are more likely to return to athletic function than are horses with clinical signs of greater than 3 months' duration.[42] The number of spinal cord compressive sites and patient age do not affect the long-term surgical outcome of cervical vertebral interbody fusion.

The duration of convalescence and rehabilitation following cervical vertebral interbody fusion is approximately 6 to 12 months.[41,42] One should design an individualized exercise program—dependent on capability, projected use, and neurologic status of the horse—for promotion of muscular strength. Extended exercise at slow speed, including ponying and lunging on inclines, is recommended during the rehabilitation process. One should determine the point at which the horse is competent to return to athletic function following interbody fusion by neurologic examination. Significant improvement in neurologic status likely will not occur beyond the 1-year postoperative period.

Successful conservative management of CSM has been achieved using the paced diet program in foals less than 1 year of age. The goal of this dietary program is to retard bone growth, enhance bone metabolism, and allow the vertebral canal diameter to enlarge to relieve compression of the spinal cord.[29,30] This dietary program is restricted in protein and energy (65% to 75% of NRC recommendations) but maintains balanced vitamin and mineral intake (at least 100% of NRC recommendations). Vitamins A and E are provided at 3 times the NRC recommendations and selenium is supplemented to 0.3 ppm. Roughage is provided by low-quality (6% to 9% crude protein) timothy hay. Individual dietary plans are specially formulated according to the age and weight of the foal. Solitary stall confinement is recommended to reduce the risk of spinal cord compression caused by dynamic instability. This program of dietary management and restricted exercise has been successful in preventing the development of neurologic signs in foals with radiographic evidence of CSM and in treating foals demonstrating clinical signs of CSM.

10.9—Equine Degenerative Myeloencephalopathy

Hilary K. Matthews

Yvette S. Nout

598

599

Equine degenerative myeloencephalopathy (EDM) is a noncompressive, diffuse, symmetric, degenerative neurologic disease characterized by ataxia, weakness, and spasticity (hypometria) in young horses of many breeds and both sexes.[1–5] Similar if not identical syndromes have been observed in Mongolian wild horses *(Equus przewalskii)*[6] and Grant's zebras.[2,7] Neuroaxonal dystrophy (NAD) can be considered a specific form of EDM in Morgan horses. NAD is clinically indistinguishable from EDM; however, histologic lesions are confined to the cuneate and gracilis nuclei of the caudal myeloencephalon, whereas in horses with EDM, lesions are found throughout the spinal cord and brainstem.[8,9]

599

600

EDM has been diagnosed in horses in Europe and North America and is reported to occur more frequently in the northeastern United States.[4] The pathogenesis of the disease is unknown but likely is caused by many factors. Currently, a dietary vitamin E deficiency in genetically predisposed animals is thought to be the most important.[10,11] A familial tendency to develop EDM has been observed in the Arabian,[2] Thoroughbred,[10] Paso Fino,[10] Appaloosa,[12,13] and Standardbred[10] breeds and in Grant's zebras.[10] NAD in Morgan horses also appears to have a familial occurrence.[14] Although a familial occurrence suggests a genetic cause, this is so far unproven.

10.9.1 Clinical Signs

The age of onset of clinical signs varies from less than 1 month to several years. Most horses manifest signs at less than 6 months of age with the mean age of onset being 0.4 year.[1,3] However, in one study of 128 horses with EDM, age of onset ranged from 1 month to 20 years, with 16% of the horses showing signs at greater than 28 months of age.[14]

Onset of signs may be abrupt or insidious.[1,2,4] Signs are referable to upper motor neuron and general proprioceptive deficits and include symmetric ataxia, weakness, and spasticity of all limbs, often being worse in the pelvic limbs.[1–5] Signs may begin in the pelvic limbs and progress to the thoracic limbs. The gait is characterized by dysmetria and stabbing of the ground with the limbs. Hindlimb interference and dragging or scuffing of the toes often are present. When backed, the horse may resist or rock back on the pelvic limbs and sit like a dog.[2,4] Postural placing reactions may show conscious proprioceptive deficits. When circled, affected horses often pivot on the inside hindlimb and circumduct the outside limb.[4] Affected horses may have trouble stopping, and for them to fall while running in the pasture or being worked is not unusual.[3,4] Cranial nerve involvement, muscle atrophy, or changes in skin sensation or tail tone are absent in EDM.[1,2] One may find lower motor neuron signs such as hyporeflexia over the neck and trunk with diminished to absent cervical, cervicofacial, cutaneous trunci, and laryngeal adductor reflexes, especially in severe and long-standing cases.[15]

NAD in Morgan horses has similar clinical signs, but even in severely affected horses, only pelvic limb deficits may be apparent. Pelvic limb dysmetria, asynchrony, and ataxia are generally less severe than in EDM.[13]

10.9.2 Pathologic Findings

Gross necropsy findings in EDM are unremarkable. Classic histologic changes are evident in the caudal brainstem nuclei (medulla oblongata) and especially the spinal cord and include diffuse neuronal fiber degeneration (dystrophy) of the white matter. Generally, EDM affects the lateral and medial cuneate nuclei, gracile nucleus, lateral cervical and thoracic nuclei, and lumbosacral and cervical intermediate gray columns. Astrocytosis, astrogliosis, vacuolization, myelin loss, spheroid formation (axonal swelling), and lipofuscin-like pigment accumulation are present in these areas. With chronicity the dorsal and ventral spinocerebellar tracts and the medial part of the ventral funiculi of the thoracic segments are affected more severely.[1,2] Neurochemical studies of the spinal cord show a significant loss of myelin and component lipids. Demyelination occurs to a greater extent than axon loss.[1]

Histologic changes in NAD of Morgan horses lack the diffuse nature of the changes in EDM. In NAD, histologic changes may be confined to the accessory cuneate nuclei.[14]

10.9.3 Pathophysiology

The pathogenesis of EDM is unknown. However, EDM most likely is caused by a complex interaction of many factors. Degenerative myelopathy in other species, which bears clinical and histopathologic similarities to EDM, has been linked to vitamin E and copper deficiencies, hereditary factors, and toxic insults.[9] Three risk factors associated with the development of EDM were identified in a study involving 56 affected and 179 control horses: (1) use of insecticides, (2) exposure to wood preservatives, and (3) spending frequent time on a dirt lot.[16]

Spending time on green pastures was found to be a protective factor. Additionally, a foal was 25 times more likely to develop EDM if its dam had any other foals diagnosed with EDM.[15] These factors alone probably do not cause EDM but may interact with other factors to produce disease. One also should consider these factors to prevent or minimize the risk of horses developing EDM.

A hypothesis for the pathophysiology of EDM is exposure of genetically predisposed young foals to environmental oxidants and lack of antioxidants, including vitamin E.[11] Oxidative stress is caused by the imbalance between production of prooxidants and the antioxidant defenses. Reactive oxygen species such as superoxide anion, hydrogen peroxide, and hydroxyl radical are formed during the reduction of oxygen to water in normal cellular metabolism (Figure 10.9-1, *A*). Aerobic cells have antioxidant defense mechanisms that protect them from oxidative stress (Figure 10.9-1, *B*). The high consumption of oxygen in the brain, high metabolic activity, and high concentration of polyunsaturated fatty acids, which can easily be oxidized to reactive oxygen species, makes the central nervous system vulnerable to oxidative attack by reactive oxygen 600
species.[9,17,18] Another source of reactive oxygen species is through the metabolism of excitatory amino acids 601
and neurotransmitters such as glutamate and aspartate. When present in excess, excitatory amino acids can trigger a series of events including an increase in intracellular calcium, which can lead to the production of free radicals and subsequent neuronal damage and death. Other sources of free radicals that arise from brain metabolism include cytochrome P-450 electron transport, monoamine oxidase activity, and endogenous guanidine compounds. Lipid peroxidation of cellular membranes and the direct oxidation of amino acids leading to inactivation of enzymes, receptors, and structural proteins are the main consequences of oxidative injury (Figure 10.9-2, *A*). More evidence indicates a role for redox signaling by oxygen radicals that targets mitochondrial cytochrome c release, DNA repair enzymes, and transcriptional factor NF-κβ. Neuronal damage occurs once these physiologic systems are disrupted.[19]

Figure 10.9-1 **A**, Physiologic metabolism of molecular oxygen to water. **B,** The mechanisms of action of four antioxidant systems. Superoxide dismutase may act as a prooxidant by increasing the formation of hydrogen peroxide and as an antioxidant by decreasing the superoxide radical concentration. Cofactors for superoxide dismutase are iron, zinc, and copper. The cofactor for glutathione peroxidase is selenium.

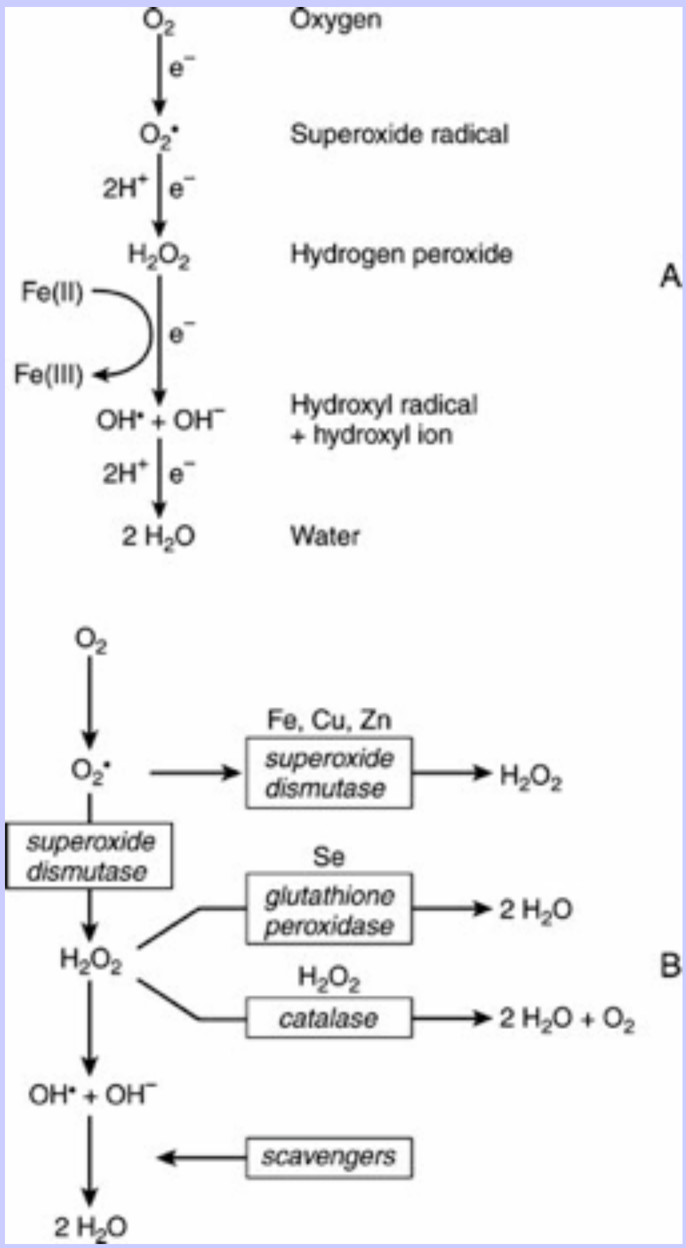

Figure 10.9-2 **A,** Mechanism of peroxidation of polyunsaturated fatty acids in cell membranes. **B,** Antioxidant mechanisms of α-tocopherol (vitamin E) and ascorbic acid (vitamin C). Polyunsaturated fatty acids are spared from oxidation because vitamin E is oxidized to a free radical instead. This prevents the propagation of lipid peroxidation in cell membranes and is referred to as the chain-breaking action of vitamin E. Vitamin C is a reducing agent that donates electrons to free radicals.

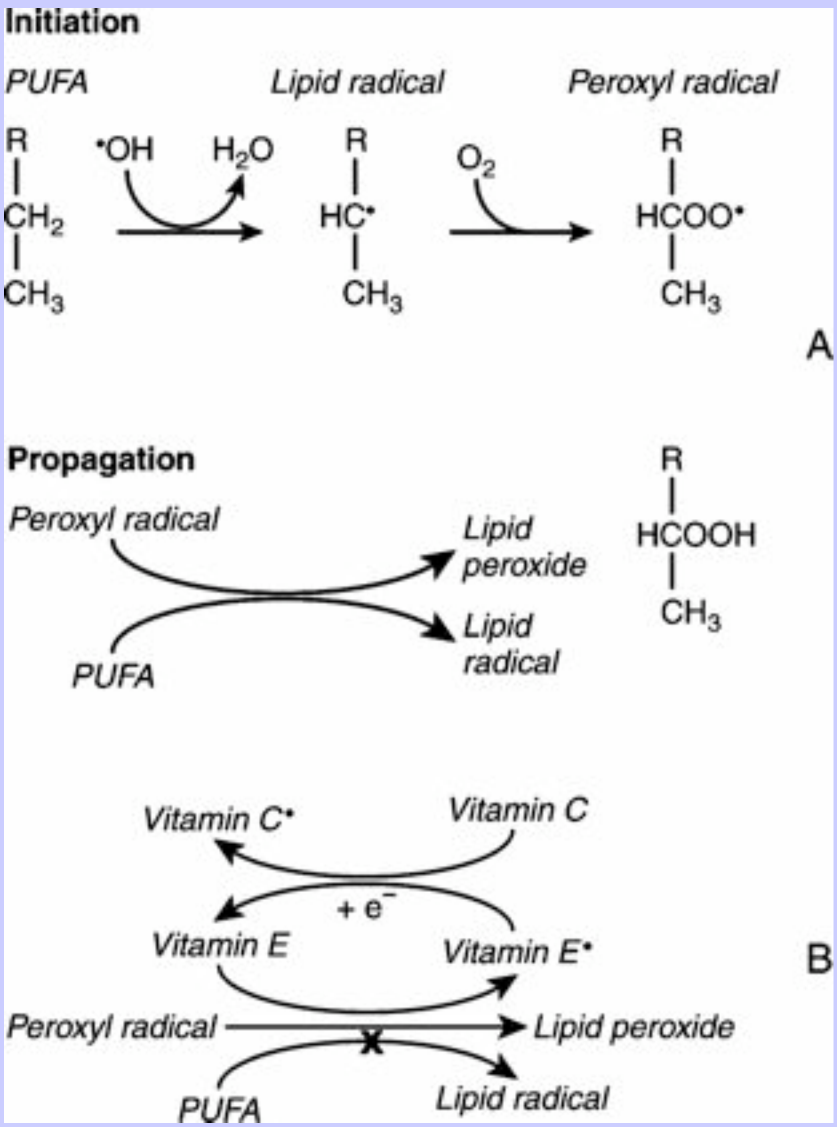

The main endogenous antioxidants are superoxide dismutase, catalase, glutathione peroxidase (that contains selenium), α-tocopherol (vitamin E), and ascorbic acid (vitamin C) (see Figures 10.9-1, *B*, and 10.9-2, *B*).[17,18] Another protective mechanism is the existence of iron-binding proteins that keep iron in a less reactive form and prevent iron from catalyzing free radical reactions. Vitamin E reacts directly with OH^- and prevents oxidant injury to polyunsaturated fatty acids and thiol-rich proteins in cellular membranes (see Figure 10.9-2, *B*).

Vitamin E deficiency has received much attention as a possible cause of EDM. This association is based on the presence of degenerative myelopathy in rats,[20,21] monkeys,[22] human beings,[23–25] and captive Przewalski's horses[6] with low serum vitamin E concentrations, the reduced incidence of EDM seen after prophylactic 601
treatment with vitamine E,[10] and the response to treatment with vitamin E in affected horses.[13] One study 602
reported a high incidence of EDM on two breeding farms in which low serum vitamin E concentrations were found. Vitamin E supplementation decreased the incidence from 40% to less than 10%. However, affected and unaffected horses on both farms were found to be vitamin E–deficient.[10] Another study found no significant differences in serum vitamin E and blood glutathione peroxidase concentrations between EDM affected horses and control horses.[26] A third study documented significantly lower vitamin E concentrations and clinical signs compatible with EDM in eight of nine foals sired by a stallion with EDM. Age-matched control foals raised in the same environment had normal serum vitamin E concentrations and no signs of EDM. Oral vitamin E absorption tests were performed on both groups, and no significant differences were found between the groups. Thus an inability to absorb vitamin E from the gastrointestinal tract does not appear to be a factor in the low serum vitamin E concentrations in horses with EDM.[27] Two other trials involving three[11] and nine[28] horses, respectively, support a role for vitamin E in the pathogenesis of EDM. Three foals developed neurologic disease and had low serum vitamin E concentrations after being housed on a dry lot. Two were examined post mortem at 6 months of age and had prominent NAD. The third foal was put onto grass pasture and recovered.[11] Nine horses with a presumptive diagnosis of EDM improved following treatment with vitamin E at 6000 IU/day.[28] The role of vitamin E or glutathione peroxidase in the development of EDM remains unclear.

Similar histologic changes and clinical signs have been observed in copper-deficient sheep,[29,30] goats,[31] guinea pigs,[32] young pigs,[33] calves,[34] and rats.[35] In one study plasma and liver copper concentrations were measured in 25 horses with histologically confirmed EDM and compared with values in 35 normal, age-matched control horses. This study found no significant differences in plasma and liver copper concentrations between the two groups.[36] Thus the role of copper in EDM remains unclear.

One also must consider hereditary factors in the pathogenesis of EDM and NAD in horses, because the diseases have been observed in familial clusters.[13] Heterofamilial NAD has been shown to occur in kittens[1,37] and Suffolk sheep[1,38] and is inherited as an autosomal recessive trait. However, the mode of inheritance has not been identified in horses affected by EDM or NAD.

Toxic compounds such as organophosphates,[1,39,40] diethyl-dithiocarbamate,[1,41] and cycad palm[42] have been reported to cause histologic changes and clinical signs similar to NAD in horses of several species. Their effect is caused by the neurotoxic properties of the compounds. No direct association of toxic compounds with EDM or NAD in horses has been shown.

10.9.4

Diagnosis

One can make a definitive diagnosis of EDM only with histopathologic examination of the spinal cord and brainstem. Antemortem diagnosis is based on clinical signs and ruling out other neurologic diseases (especially cervical vertebral malformation and equine protozoal myeloencephalitis). In EDM, cerebrospinal fluid analysis and cervical spinal radiographs are usually within normal limits, although increased cerebrospinal fluid creatine phosphokinase levels have been found in horses affected with EDM.[1] Serum vitamin E levels of less than 1 mg/ml in horses showing clinical signs of EDM may help support a diagnosis.[3]

The normal reference range for serum vitamin E concentration varies but is usually greater than 1.5 mg/ml.[3] Measuring of serum vitamin E concentrations may be unreliable when the animal is examined after the critical deficient period. Moreover, one should note a single serum vitamin E sample may not reflect the true vitamin E status of the horse adequately, for up to 12% variation in concentrations can occur normally.[43]

A diminished thoracolaryngeal reflex or slap test may raise the suspicion of cervical spinal cord disease by 50% to 70%; however, this test is not accurate, and negative results do not exclude the possibility of cervical spinal cord disease.[44]

10.9.5

Treatment and Prevention

No specific treatment for EDM in horses exists. Affected horses may benefit from oral vitamin E supplementation coupled with monitoring of serum vitamin E concentrations. The earlier vitamin E treatment is instituted, the better the chance for a response. Horses with clinical signs of EDM may benefit from large doses of vitamin E (6000 to 10,000 IU/day) for an extended time.[45] Horses with low serum vitamin E concentration also may benefit from 1000 (foals and yearlings) to 2000 (adults) IU of vitamin E in oil given intramuscularly every 10 days. One should maintain dietary vitamin E levels at 500 to 1000 IU/kg dry weight.[3] Heat-treated pellets, stored oats, and sun-baked forages have marginal vitamin E concentrations (0 to 5 IU/kg dry weight).[3,10] Horses fed a diet of these should have frequent access to fresh green forage or vitamin E supplementation at 600 to 1800 mg or tocopheryl acetate 1.5 to 4.4 mg/kg/day to meet their reported needs.[46] To date, vitamin E toxicity associated with supplementation has not been reported. Also, farms with a high incidence of EDM may benefit from prophylactic vitamin E supplementation.[10]

602

603

10.9.6

Prognosis

EDM is generally progressive, necessitating euthanasia. Once clinical signs are evident, no improvement or remission occurs. However, signs may plateau.[3,10] Generally, horses with EDM do not progress to a state of recumbency.[1,3] Severely affected horses usually have an earlier age of onset and rapid disease progression. Mildly affected horses usually have a later age of onset, and the disease has a less rapid course.[4]

10.10 10.10—Equine Protozoal Myeloencephalitis

William J. Saville

David E. Granstrom 603

604

10.10.1 History

Equine protozoal myeloencephalitis (EPM) was identified initially as segmental myelitis by J.R. Rooney at the University of Kentucky in 1964.[1] The first cases were recognized among Standardbreds returning to Kentucky from racetracks in the northeastern United States. Subsequent cases have been reported among native horses in most of the United States and in Canada, Panama, and Brazil.[2–5] Several reports of the disease in countries in other than the Western Hemisphere were primarily in horses that originated from the Americas.[6–8] The disease was called *segmental myelitis* because discrete lesions were found distributed randomly throughout the spinal cord. As more cases were examined, the frequent involvement of the brain became apparent, resulting in the name focal myelitis-encephalitis. The lesions of EPM include multifocal areas of necrosis and hemorrhage along with nonsuppurative inflammation of the white and gray matter. Ten years later, a *Toxoplasma*-like protozoan was recognized in histopathologic sections, and the disease gradually became known as equine protozoal myeloencephalitis.[9–11]

Dubey, in a 1976 review of sarcocystosis in domestic animals, was the first to suggest that EPM was caused by a member of the genus *Sarcocystis*.[12] Another 15 years passed before he was able to culture the organism from the spinal cord of an affected horse.[13] He named the organism *Sarcocystis neurona* because it often develops within neurons. Until recently, little information was available regarding the life cycle of the organism, and only asexual stages of the parasite were known. Sporocysts presumed to be *S. falcatula* isolated from opossums were tested by polymerase chain reaction assay using primer sets derived from the 18S small subunit ribosomal gene sequence of *S. neurona*. Sequence analysis of the amplicon demonstrated 99.89% homology with the 18S small subunit ribosomal DNA sequences of *S. neurona*.[14] Recognition of the definitive host led to the erroneous conclusions that the parasite had a bird-opossum life cycle.[14,15] A few years later this error was rectified when the opossum turned out to be the host of at least three *Sarcocystis* spp.[16] Recently, another protozoan parasite *(Neospora caninum/N. hughesi)* was implicated as a cause of EPM in six cases; however, its role likely is limited.[17–22]

10.10.2 Epidemiology

Most of the information known about EPM was gathered from naturally occurring infections. Regional epidemiologic studies of EPM have yielded dissimilar results.[23,24] Although regional differences occur, the first

general information for North America was collected during an EPM workshop convened at the Veterinary Medical Forum of the American College of Veterinary Internal Medicine in 1988.[25] The information was based on 364 histologically confirmed cases from California, Florida, Illinois, Kentucky, New York, Ohio, Oklahoma, Pennsylvania, and Texas and Ontario, Canada. Data were compiled from histologically confirmed cases from animal diagnostic centers in each state or province. The average period reported was 6 years with a range of 4 to 12 years. In descending order of frequency, Thoroughbreds, Standardbreds, and Quarter Horses were affected most often, although many other breeds and ponies were represented. Usually only one animal in a herd or location was affected. The age of affected horses ranged from 2 months to 19 years, but more than 60% were 4 years old or less. No geographic or seasonal predilection could be established.

Preliminary seroprevalence data were collected using immunoblot testing to detect antibodies to *S. neurona*–specific proteins in equine serum samples (Granstrom, unpublished). Initial testing in Kentucky and Ohio 604
detected an average exposure rate greater than 20% among clinically normal horses. Subsequent investigations 605
conducted at the University of Kentucky laboratory on serum samples collected from horses in Ohio, Kentucky, and Pennsylvania have demonstrated exposure rates greater than 40% among clinically normal horses. Exposure rates on individual farms ranged from no exposure to 100%. The seroprevalence from a small study from one county in Pennsylvania was 45% of the horse population (95% confidence interval equals 36.3% to 54.3%) along with an increase in prevalence with age.[26] Another report from Oregon found an overall seroprevalence of 45% among horses with differences in seroprevalence among geographic regions.[27] The seroprevalence ranged from 22% in the eastern arid region of the state to 65% in the coastal region of Oregon. A third study from Ohio reported a prevalence of serum antibodies to *S. neurona* in horses at 53.6%. The study from Ohio demonstrated an increase in prevalence with age of the horse and greater prevalence in southwest Ohio versus northeast Ohio. These differences in prevalence may have been related to climatic differences based on freezing days in various regions of the state.[28] In a more recent study, antibodies to *S. neurona* were found in 33.6% of various equid serum samples submitted to a laboratory in Colorado. As in other seroprevalence studies, the prevalence increased with age; in 1- to 5-year-old horses, prevalence was 26.0% versus 37% in 10-year-old horses. Seroprevalence was lowest during the colder months, as has been determined in other states.[29] Results on clinical samples submitted to the University of Kentucky for EPM testing suggested that horses in the eastern half of the United States are exposed to *S. neurona* at a rate 10% to 15% higher than those in the western half of the country.[30] Recent reports suggest that the prevalence of *S. neurona* antibody in horses in Argentina and Brazil are 35.5% and 35.6%, respectively.[31,32] Little work has been performed regarding the prevalence of antibody to *N. caninum/N. hughesi* in horses. More recent work found a seroprevalence of 23.3% in sera examined from two horse slaughterhouses in the United States and no antibody detection in Argentina and Brazil. Because few horses were sampled, these studies may not reflect the true prevalence of *N. caninum/N. hughesi* antibody in horses.[31–33] These results suggest that exposure to *S. neurona* is common in some areas, but much more work needs to be done regarding *N. caninum/N. hughesi* exposure.

In 1978, the New York State Veterinary College at Cornell University, Ithaca, reported that 25% of all equine neurologic disease accessions were caused by EPM.[24] The number of cases diagnosed at the Livestock Disease Diagnostic Center at the University of Kentucky, Lexington, has been 8% to 9% of all neurologic accessions over the last few years. A recent report from the Ohio State University Veterinary Hospital, Columbus, revealed a 25% incidence of EPM in all horses with spinal ataxia from December 1991 to March 1994 based on Western blot analysis of serum and cerebrospinal fluid (CSF).[34] Determining whether the increase is real or is caused by heightened awareness resulting from the availability of immunoblot testing of serum and CSF is difficult. Horses that actually reach the postmortem room represent a small portion of the total number affected annually. Granstrom and Saville estimated the incidence of EPM based on accessions to the University of Kentucky

diagnostic laboratory was 1% of all horses or less each year.[35] Based on a recent national study conducted by the U.S. Department of Agriculture, the average incidence of EPM was 14 ± 6 cases per 10,000 horses per year. The incidence, based on primary use of the horse on the operation, found that the lowest incidence was in farm/ranch horses (1 ± 1 cases/10,000 horses/year). Incidence increased in pleasure horses to 6 ± 5 cases/10,000 horses/year, with a significant increase in breeding horses (17 ± 12 cases), racing horses (38 ± 16 cases), and competition/show horses (51 ± 39 cases), although the racing horses did not include horses at racetracks.[36] These estimates reflect a similar incidence of the disease as previously reported, if not lower. The incidence of neosporosis in horses is unknown at the present time because no controlled investigations have been performed. A total of six case reports of neosporosis in horses indicate the cause as *N. caninum (N. hughesi)*.[17–22] However, only four reports indicated neurologic signs were found; one was in an aborted fetus and another was related to an intestinal problem.[17–22]

EPM has been reported from Canada, Mexico, Panama, Argentina, and Brazil and from a number of states in the United States.[2,4–6,37,38] EPM also has been reported in England among horses imported from the eastern United States and in an 8-month-old Arabian horse in South Africa that had been imported from the United States approximately 5 months before the onset of signs.[7] The most recent report was a horse from California that developed clinical signs of EPM after 10 months in Hong Kong.[8] These reports suggest that EPM is primarily a disease of the Western Hemisphere.

Several authors have suggested Standardbred horses may have a higher prevalence of disease.[23,39–41] However, other reports suggest that this apparent prevalence may be caused by the environment in which horses were kept rather than breed characteristics.[23,40] In another case series, EPM was reported to be most common in Thoroughbreds; however, this was not a controlled investigation.[25] A more recent controlled investigation of risk factors for the development of EPM found that occupations such as racing and showing were associated with increased risk compared with breeding and pleasure horses.[42] This finding was corroborated by the incidence of 605
EPM reported in the National Animal Health Monitoring System (NAHMS) study.[36] 606

Early reports suggested that young horses had an increased disease risk; at least 60% of the affected horses were 4 years old or younger.[23,25,39] This increased risk in young horses also was found in the controlled epidemiologic study in Ohio.[42] However, the Ohio study also found an increased risk in horses older than 13 years of age.[43]

Historically, EPM has been reported as a sporadic disease with more than one case uncommonly reported on any one farm.[40,44] In contrast, reports of EPM cases from Panama stated that all affected horses were stabled at the same location.[4] A more recent report also described an outbreak on a farm in Kentucky.[45] In Ohio, previous diagnosis of the disease on the farm (>2.5 times higher) suggested an increased risk for EPM. This finding suggests clustering of cases may occur when all the risk factors for EPM are present.[42]

Several other risk factors for development of EPM were reported; for example, an increased risk if opossums were seen on the farm, if woods were present on the farm, or if seasonal effect or occurrence of a health event happened before development of clinical signs of EPM. Compared with the winter the seasonal effect increased the risk of EPM as the temperature increased, with the highest risk in the fall. The risk also decreased if a creek or river was present on the farm and if the feed was kept protected from wildlife access, according to the Ohio study.[42] In concert with the Ohio study, the NAHMS study also found, compared with never seeing an opossum on the premises, an increased risk if opossums were observed on the premises and even higher risk if the

opossums were seen frequently. Additional risk factors included an increased risk with increased numbers of horses, purchased versus home-grown grain, use of wood chips or shavings as bedding, presence of rats and mice on the premises, and increased human population density. A protective effect was apparent when woods were within 5 miles of the premises and where surface water was the primary drinking source. The NAHMS study also found the highest risk for disease was in the fall of the year.[36] The role that management may play in development of clinical EPM is patently obvious.

10.10.3 Cause and Life Cycle

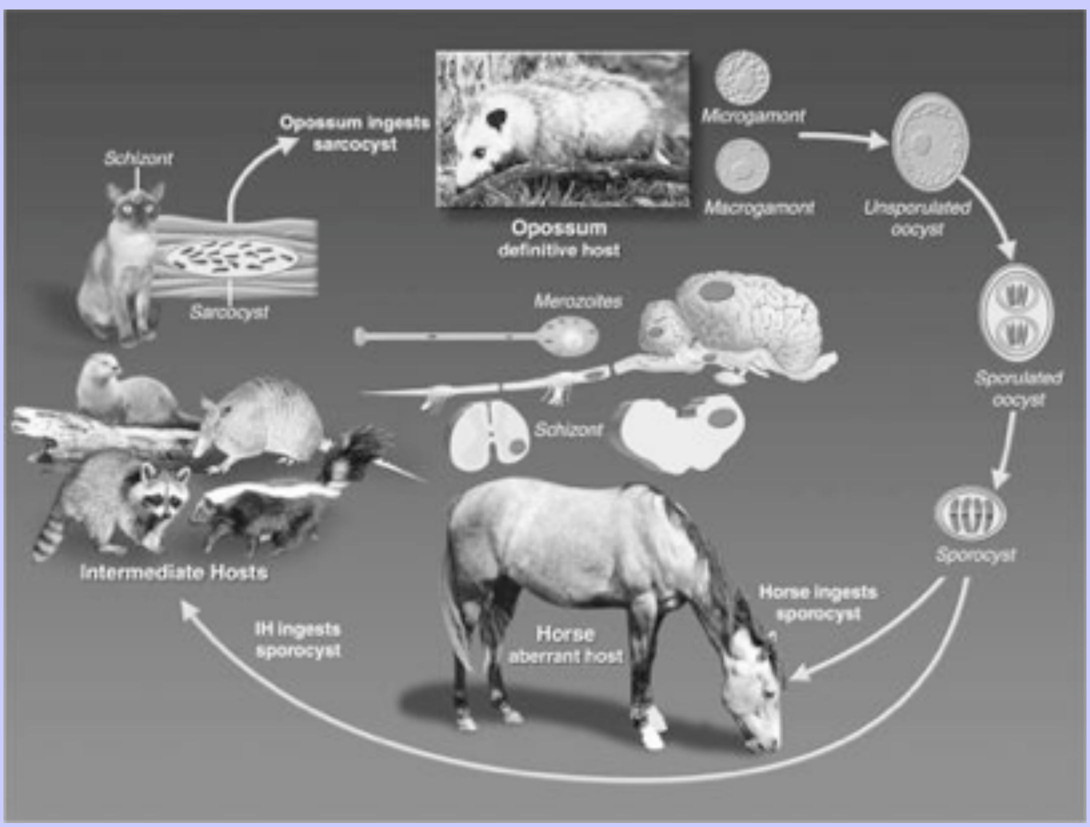
S. neurona has been cultured from CNS lesions of nine horses from several different locations: New York,[13] California (three cases),[46,47] Panama,[4] Kentucky (three cases),[48] and Missouri.[49] Preliminary morphologic, immunologic, and DNA comparisons have detected only minor differences among isolates.[4,48] Cultured organisms multiply asexually by a type of merogony (or schizogony) known as endopolyogeny, whereby many merozoites (or tachyzoites) are formed from a single nucleus.[13] Endopolyogeny contrasts with endodyogeny, the method of merogony that produces merozoites of *Toxoplasma gondii*. As the term implies, each individual *Toxoplasma* merozoite divides to form two new merozoites. The term *meront* (or *schizont*) refers to the small intracellular body of rapidly budding merozoites seen in histopathologic sections and in cell culture. Cultured merozoites contain a conoid, numerous micronemes, and a central nucleus, but no rhoptries.[4] This stage of *Sarcocystis* species is not known to be transmissible to other animals. Cultured merozoites have been injected epidurally, intramuscularly, intravenously, and subcutaneously without producing clinical signs in normal horses (Granstrom, unpublished). A recent study has corroborated that epidural injection of merozoites does not result in clinical signs of EPM.[50] Transplacental infection has not been reported but cannot be ruled out.

Sarcocystis belongs to the phylum Apicomplexa, which includes several genera of coccidia that use an obligatory predator-prey or scavenger-carrion life cycle.[3,51] The host range for an individual species of *Sarcocystis* is usually narrow. *Sarcocystis* species produce sporulated oocysts by sexual reproduction (gametogony) in the gut wall of the appropriate predator or definitive host. However, the oocyst wall is fragile and usually ruptures before being passed in the feces. Infective sporocysts are introduced into the food and water supply of the prey animal or intermediate host by fecal contamination from the predator. Birds and insects may serve as transport hosts to disseminate sporocysts further.[52,53] Once ingested by the intermediate host, sporocysts excyst, releasing four sporozoites that penetrate the gut and enter arterial endothelial cells in various organs. Meronts develop rapidly and eventually rupture the host cell, releasing merozoites into the bloodstream, which usually is followed by a second round of merogony in capillary endothelial cells throughout the body. Second-generation merozoites are released into the bloodstream and usually enter skeletal muscle cells where they develop into specialized meronts known as sarcocysts. Mature sarcocysts contain bradyzoites, which are able to complete the life cycle only when ingested by the appropriate predator or scavenger. *Sarcocystis fayeri* uses this general method to cycle between horses and canids and is not pathogenic in either host.[3] The prevalence of *S. fayeri* in North America has been estimated at approximately 30%, increasing with age.[54]

S. neurona may infect a large number of intermediate hosts aberrantly, unlike most *Sarcocystis* spp. Several species of animals and birds have been reported to exhibit symptoms similar to those in horses with EPM. 606
Reports indicate that an *S. neuron*–like organism infects and causes neurologic disease in dogs, sheep, cats, 607
mink, raccoons, a striped skunk, a golden hawk, pacific harbor seals, sea otters, chickens, and a Grant's zebra.[55–66] This wide host range is atypical for *Sarcocystis* spp, similar to that of *T. gondii,* which is phylogenetically close to *S. neurona*.[3,67]

Sarcocysts of *S. neurona* have not been found in affected horses, precluding transmission of the parasite to the definitive host.[3,54] The horse is an aberrant, dead-end host.[51,54] *S. neurona* cycles between the opossum and various intermediate host species (Figure 10.10-1). Sarcocysts are found in the muscles of infected domestic cats *(Felis domesticus)*, nine-banded armadillos *(Dasypus novemcinctus)*, striped skunks *(Mephitis mephitis)*, raccoons *(Procyon lotor)*, and sea otters *(Enhydra lutris nereis)*.[68–71] At first the domestic cat was thought to be only a laboratory intermediate host; however, a study in Missouri and another in Ohio suggest that the cat is a natural intermediate host as well.[72,73] The same holds true for the striped skunk. The life cycle of *S. neurona* has been completed in a laboratory setting.[70] However, previous reports of serum prevalence of antibodies to *S. neurona* in striped skunks (22 of 37) would suggest they are likely a natural intermediate host as well.[74] Muscle from wild-caught raccoons and road-killed armadillos fed to laboratory-raised opossums resulted in shedding of 607
sporocysts infective for ponies, horses, and IFN-γ/KO mice.[69,71] In addition, high seroprevalence of *S. neurona* 608
antibodies in armadillos (100%) tested from three states and raccoons (58.6%) tested from four states further suggests that these species are natural intermediate hosts.[69,75] Opossums shed sporocysts in their feces following ingestion of the infected muscle. Small numbers of sporocysts were found after feeding sea otter muscle infected with *S. neurona* sarcocysts to opossums; however, the sporocysts were infective for IFN-γ/KO mice. The role of the sea otter as a natural intermediate host likely is limited. This, however, demonstrates that many species may be potential intermediates hosts for this organism.

Figure 10.10-1 Life cycle of *Sarcocystis neurona*. (Photo courtesy Dr. William J.A. Saville, The Ohio State University, Columbus, Ohio.)



The life cycle of *N. caninum* or *N. hughesi* in horses is understood poorly. Recently, the definitive host of *N. caninum* has been demonstrated to be the dog,[76] but whether the dog is the definitive host of *N. hughesi* is not known. Similar to *T. gondii* in cats, the dog serves as the definitive host and one of several known intermediate hosts for *N. caninum*. Tachyzoites, as well as tissue cysts, have been found in other horse tissues in two of the horses reported to have EPM caused by *Neospora,* unlike EPM caused by *S. neurona*.[77] In one case of neosporosis, a foal was determined to have been infected congenitally, whereas congenital infections have not been demonstrated in horses infected with *S. neurona* up to the present time.[20]

The clinical severity of experimental sarcocystosis in appropriate intermediate hosts studied is related directly to the number of sporocysts fed.[78] The ability of any individual to resist infection appears to be related to the size of the infective dose, immunocompetence, environmental stress, and the species of *Sarcocystis*. Some individuals may be inherently more susceptible to infection, which may have variable heritability. Speculation about this possibility seems premature until more is learned about the pathogenesis of clinical infection.

Several studies have induced experimental infection in horses using *S. neurona* sporocysts. The first study was done at the University of Kentucky. Naïve foals were infected orally with 1×10^6 to 4×10^7 sporocysts, resulting in mild to moderate neurologic deficits. In this study, sporocysts were collected from wild-caught opossums, cleaned, and administered via nasogastric intubation. Parasites could not be cultured from the central nervous system tissues; therefore Koch's postulates were not fulfilled.[79] Three studies from the University of Florida were conducted using characterized sporocysts detected using molecular DNA probes.[80] One study administered 1×10^6 *S. neurona* sporocysts once, and another study was performed in which 5×10^5 sporocysts were administered orally once daily for 7 consecutive days; both resulted in mild to moderate neurologic deficits and no parasite was detected.[81,82] Sporocysts characterized as *S. falcatula* were administered to horses and resulted in no development of neurologic signs or seroconversion.[83] These findings corroborated that the opossum excreted more than one *Sarcocystis* spp. of sporocysts. Recently, another study attempted to infect horses using 8×10^4 *S. neurona* sporocysts with three different treatment groups. All nine horses in the study that were infected developed neurologic signs; however, the most severe signs (mild to moderate) were seen in horses in the transport stress group.[84] Unfortunately, parasites could not be cultured from the CNS tissues. All three studies attempted to mimic stress using dexamethasone; however, the clinical signs were less severe, and the clinical signs of the horses appeared to improve. Additionally, in all three studies, regardless of the dose of sporocysts administered, some horses demonstrated an improvement in their clinical signs in the face of no treatment.[79,82,84] The improvement suggests that horses are capable of clearing large numbers of these organisms, which may explain the high number of clinically normal horses with parasite-specific antibody in the CSF. More troublesome is the fact that after orally inoculating horses with 1×10^8 *S. neurona* sporocysts, clinical signs of neurologic deficits were readily detectable, but parasites were not found in the central nervous system at 7 or 14 days after infection (W.J.A. Saville and J.P. Dubey, unpublished observations). This result is unlike the *S. neurona* infection in the natural intermediate host, raccoon, in which the parasite was readily detectable in the CNS at 7 days after infection.[85] The life cycle of *S. neurona* in the horse remains enigmatic.

The organism may be transmitted via methods other than direct contact with opossum feces, based on the estimated numbers of opossums in North America, their poor survival, and limited individual range. Experiments performed by researchers in the 1980s suggest that birds may help disseminate sporocysts.[86] Secondary or vector transmission also was demonstrated by the recovery of sporocysts in the feces of budgerigars, canaries, mice, and chickens fed opossum feces. Recovered sporocysts then were fed to budgerigars to assess viability following

transit through the digestive tract of those species. Four of six budgerigars died, suggesting that sporocysts disseminated in this way may be transmitted to intermediate hosts.[52] Considering the apparent wide range of natural and aberrant intermediate hosts of *S. neurona* indicates that control of the disease may be difficult.

Insects such as flies and cockroaches also may be transport vectors for *S. neurona,* for early work demonstrated that flies may act as transport vectors for *T. gondii*.[87] The same group also found that cockroaches may act as transport vectors for *T. gondii*.[88] More recently, fatal pulmonary disease developed in psittacine birds that were fed cockroaches after the cockroaches had been fed opossum feces.[53] This suggests that insects may play a role in transmission of *S. neurona;* however, further investigation is necessary to determine which insects actually are involved in the life cycle of this organism, if any.

10.10.4 Clinical Signs

The clinical signs associated with *S. neurona* infection can vary. This variability simply reflects the multifocal or 608
diffuse distribution of the lesions that may occur randomly in the gray and white matter of the brain, brainstem, 609
or spinal cord. Usually the physical examination is within normal limits, and the horse appears bright and alert, although one may observe focal muscle atrophy. The onset of clinical signs may be gradual, but more typically mild signs develop acutely and may progress rapidly. The neurologic examination often reveals ataxia and incoordination in all limbs, which sometimes show lateralization, or gait abnormalities may be apparent with only one limb involved. Infection with *S. neurona* can result in brainstem and spinal cord signs and often causes damage to the lower motor neuron of spinal cord or cranial nerves, leading to muscle atrophy. Muscle atrophy is most common in the quadriceps and gluteal regions in the hindlimbs but also may mimic sweeney, radial paralysis, or polyneuritis equi. If the brainstem is involved, atrophy of the temporal-masseter muscles and occasionally the tongue may be evident along with head tilt, facial nerve paralysis, and difficulty swallowing.[89,90] Carefully examining for signs of muscle wasting and loss of sensation along the face, neck, or body is important.

A frequent complaint is obscure lameness that may progress to ataxia, spasticity, and incoordination of the limbs. Poor coordination and weakness worsen with walking with the head elevated or walking up or down a slope. The asymmetry of clinical signs may be an important early indication of EPM. Horses with brainstem involvement often have head tilt, facial paralysis, loss of sensation of the cornea and internal nares and also dysphagia, circling, and acute recumbency.[24,40] Some horses have a tendency to lean toward the side of the lesion and use the wall of the stall to balance themselves. At least three horses have been observed with seizures as the only clinical signs.[91] Visual deficits and behavioral abnormalities have been reported in some horses with EPM.[89] A recent case series reported head shaking in three horses diagnosed with EPM. After treatment for EPM, the head shaking resolved in these horses.[92]

10.10.5 Pathogenesis and Pathology

The pathogenesis of EPM is understood poorly, but one assumes that the horses ingest *S. neurona* and that the course of infection and disease is then similar to that observed in other host species infected with *Sarcocystis* spp. Sporocysts of *S. neurona* are passed in the feces of the opossum and introduced into the feed and water supply of intermediate hosts. On reaching the gastrointestinal tract, sporocysts excyst, releasing eight sporozoites that penetrate the gut and enter arterial endothelial cells in various organs. Meronts develop within host cells, resulting in cell rupture and release of merozoites into the bloodstream. A second round of merogony may follow in vascular endothelial cells throughout the body. In the appropriate intermediate host a final round of merogony

results in the formation of sarcocysts in various muscles. The predator or definitive host subsequently ingests the infected muscle tissue to complete the life cycle. At the present time, sarcocysts of *S. neurona* have not been found in affected horses, indicating that the horse is likely an aberrant, dead-end host.[35]

Many normal foals have been produced by mares suspected of having EPM. Recently, an infected pregnant mare was euthanized and the diagnosis was confirmed histologically. The foal, taken at euthanasia, died of pneumonia at 8 weeks of age without neurologic signs. No lesions were present in the CNS. Although the mare was immunoblot positive in serum and CSF, the foal was immunoblot negative. The earliest EPM case reported occurred in a 2-month-old foal.[25] If transplacental transmission does not occur, the minimum incubation period may be 8 weeks. However, a recent case suggests the incubation period may be much shorter. Serum and CSF collected 4 days after onset of clinical signs were negative for antibodies to *S. neurona*. Serum and CSF collected 3½ weeks later were positive. The results indicate that the parasite was ingested and caused clinical signs in the 10 to 12 days required to produce a detectable antibody response.

S. neurona has been recovered from CNS lesions in several horses and subsequently propagated in culture in the laboratory, which has enabled development of diagnostic tests. Cultured merozoites have not induced clinical disease in the horse when administered to horses parenterally or introduced via the epidural space.[93] The results have been corroborated by others.[50] The merozoite stage of *Sarcocystis* spp. is not known to be transmissible to other animals either[93]; however, nude mice have been inoculated intraperitoneally with cultured merozoites and subsequently have developed evidence of *S. neurona*–associated encephalitis.[94] These mice were immunosuppressed strains, and intraperitoneal injection likely would not be the normal route of infection with *S. neurona* in horses. Recently, another mouse model was developed by feeding sporocysts from feral opossums to IFN-γ/KO mice. Use of IFN-γ/KO mice also help to differentiate *Sarcocystis* spp. that are excreted in opossum feces, for at least three species appear to be present.[95] The mechanism is currently unknown by which the merozoites enter the CNS. The organism is believed to enter the CNS via infected leukocytes or directly through the cytoplasm of endothelial cells.[93]

Affected horses often have a history of recent stress; for example, shipment, heavy training or racing, and foaling. Many affected horses have been moved frequently, making determining where exposure occurred difficult. If the onset of clinical signs is stress-related, the incubation period and seasonal occurrence would vary 609
greatly. Clinical signs are confined to the central CNS and may include seizures and cranial nerve or spinal cord 610
signs. Affected horses may stumble and fall or show weakness, ataxia, and spasticity in one or more limbs.

One hypothesis suggests that stress may play a role in the development of EPM,[3,35] but limited evidence is available to support this hypothesis. The size of the infective dose, immune competency of the host, and the environmental stresses to which the horse is exposed may be related to the severity of EPM.[93] An association between immunosuppression and disease has been documented in other species with EPM-like symptoms; for example, recent mouse models for the disease have been developed using nude mice and IFN-γ/KO mice, both of which are immune-compromised strains.[94,95] Raccoons have been identified that were infected concurrently with a *Sarcocystis* spp. and canine distemper virus.[63,96] Canine distemper virus is known to be immunosuppressive and often has been associated with cerebral toxoplasmosis in dogs, foxes, and raccoons.[96] In a monkey that developed asymmetric neurologic signs similar to those in EPM, *Sarcocystis* spp. infection of the CNS also was identified with a concurrent simian immunodeficiency virus infection.[97] Immune-compromised human beings often are infected with *T. gondii*. Stress has been demonstrated to play a major role in the recrudescence of the clinical signs of *T. gondii*–associated encephalitis.[98] Infections with *N. caninum* or *T. gondii* can cause T cell

hyporesponsiveness to the parasite antigen in laboratory animals. In addition, an intact T cell response, specifically appropriate interleukin-12 and interferon-γ production, has been demonstrated to be necessary for resistance against *N. caninum* or *T. gondii*.[99] *S. neurona* behaves similarly to *N. caninum* and *T. gondii* in its wide range of intermediate hosts. Perhaps *S. neurona* facilitates further infection by compromising host immune responses. Recent evidence suggests that neuropeptides (neuroimmune proteins) are released from the CNS when an animal is stressed. Neuroimmune proteins may lead to suppression of lymphocyte production and function. Stress leads to high circulating glucocorticoid concentrations that are also immunosuppressive.[100] Perhaps the combination of high resting concentrations of glucocorticoids and release of neuroimmune proteins result in immunosuppression and facilitate development of clinical disease in horses infected with *S. neurona*. Recent evidence from a controlled investigation performed at Ohio State University demonstrated that health events before diagnosis of EPM were associated strongly with the disease.[42] Other evidence that stress may play a role in the pathogenesis of EPM results from transport stress and induction of the disease in an experimental equine model of EPM.[84] Transport has long been known as a stressor in horses and other species.[101–105] Horses are transported year-round to equestrians events in the United States. Further controlled investigations are needed to examine the role of stress in the development of clinical signs of EPM in horses.

S. neurona probably causes few pathologic changes in immunocompetent intermediate hosts. However, CNS lesions in the horse are often extensive.[9–11,24] Multifocal areas of hemorrhage to light discoloration of the brain or spinal cord may be visible on gross examination. Lesions may be microscopic to several centimeters wide. The brainstem and spinal cord are affected most often. Microscopically, lesions are characterized by focal to diffuse areas of nonsuppurative inflammation and necrosis with perivascular infiltration of mononuclear cells, including lymphocytes, macrophages, and plasma cells. Giant cells, eosinophils, and gitter cells also are present in inflammatory infiltrates. Gray or white matter or both are affected. Organisms have been found in neurons, leukocytes, and vascular endothelium, although they tend to develop most often in neurons[*]

* References 9, 10, 13, 24, 37, 38, 46, 106, 107.

10.10.6 Diagnosis

Immunoblot analysis of serum and CSF provides antemortem information regarding exposure to *S. neurona*.[108] The test uses cultured merozoites to detect antibodies directed against proteins considered unique to *S. neurona*. Antibodies produced to proteins shared with *S. fayeri* or other organisms found in North America can be differentiated. Other types of immunoassays are confounded by cross-reactivity with *S. fayeri* or other organisms that share antigens with *S. neurona*. Immunoblot testing of CSF samples has demonstrated greater than 90% specificity and sensitivity among approximately 300 neurologic cases that received postmortem examination. Approximately one half of the cases were confirmed histologically as EPM. Positive serum (specific antibody present) indicates exposure only. However, greater than 90% of histologically confirmed cases have tested seropositive.

Positive CSF indicates that parasites have penetrated the blood-brain barrier and stimulated a local immune response. If the integrity of the blood-brain barrier is compromised, circulating antibodies may leak across and produce a false-positive test result. Determination of total immunoglobulin G (IgG) and albumin in serum and CSF in such cases may be helpful. If the ratio of total IgG in CSF and serum is normal (IgG index) with an increase in blood-brain permeability (designated by the albumin quotient), leakage may have occurred. However, 610
if the albumin quotient is normal or increased, along with an increase in the IgG index, intrathecal antibody 611
production is likely, which may be caused by the presence of parasites in the CNS.[109] Unfortunately, immunoblot sensitivity exceeds that of the IgG index. CSF samples from horses with particularly high amounts

of circulating anti–*S. neurona* antibodies present the greatest potential for undetectable serum leakage using the IgG index. False-negative results have been rare but may occur. Some horses simply may fail to respond to the *S. neurona*–specific proteins identified.

The possible causes of false-negative responses are important to consider so that one does not misdiagnose affected horses. Horses that initially tested positive have become negative after several weeks of treatment and apparently have recovered. Chronically affected horses may test negative and still be infected, or the horse still may exhibit neurologic signs. The authors speculate that this may be caused by permanent CNS damage and that parasites are no longer present or antibody production is below test sensitivity. The use of polymerase chain reaction testing may aid in parasite detection when CSF antibody concentration is low. One should retest acute cases that test negative in 2 to 3 weeks. However, the incubation period appears to be sufficiently long to allow production of detectable amounts of IgG before the onset of clinical signs in most cases. As discussed previously, one exception with a short incubation period has been observed. Additional positive reactions were not observed when the immunoblot assay was modified for the detection of IgM.

10.10.7 Differential Diagnosis

Differential diagnoses for EPM include any disease affecting the CNS, although the results of neuroanatomic localization often make some more probable. For example, a horse with weakness, ataxia, and spasticity of all limbs and with no muscle atrophy or cranial nerve deficits suggests cervical vertebral stenotic myelopathy or equine degenerative myeloencephalopathy.[24,40,106,110] Both diseases affect young horses (1 to 3 years of age), but cervical vertebral stenotic myelopathy occurs more often in males. The clinical signs are often symmetric, with the hindlimbs usually a grade worse than the forelimbs.[24,106,110] Signs may be exaggerated by flexing or hyperextending of the neck.[24,110]

Equine herpesvirus (type 1) myeloencephalitis often has an acute onset following an episode of fever, cough, and nasal discharge or following one or more abortions on a farm. This condition often affects more than one horse on a farm. Herpesvirus has a rapid onset and often results in severe hindlimb weakness and ataxia along with bladder dysfunction. Urine dribbling sometimes may occur. Ataxia and weakness usually are symmetric and may result in recumbency. Occasionally, affected horses sit like dogs. Cranial nerve involvement is not common.[111–114]

Another disease one must consider in the differential diagnosis for EPM is polyneuritis equi. This disease can occur acutely and insidiously. Polyneuritis equi is more common in mature horses and usually starts with hyperesthesia progressing to anesthesia. Progressive paralysis of the tail, rectum, bladder, and urethra occurs, leading to urine dribbling. Rearlimb ataxia with gluteal atrophy may be present. Asymmetric cranial nerve deficits with involvement of cranial nerves V, VII, and VIII have been reported in 50% of the cases.[115–118]

One also should consider verminous myeloencephalitis, for the signs vary depending on the migratory pathway of the parasite. Diffuse or multifocal brain and spinal cord lesions have been reported. The onset is usually sudden, with rapid deterioration and death. The incidence of this disease is low, perhaps because of more intense parasite control.[119–121]

Over the last 3 years, another disease has become the number one differential diagnosis for EPM. West Nile virus was first reported in the United States in 1999, and the number of equine cases has gone from 25 in 1999 to 60 in 2000 to greater than 550 cases in 2001. Most of the equine cases in 1999 were diagnosed with EPM first before a definitive diagnosis of West Nile virus was determined, which demonstrates their similarity.[122]

Asymmetric neurologic deficits with profound weakness and ataxia makes differentiating West Nile virus from EPM difficult without the aid of ancillary diagnostic testing.

10.10.8 Treatment

Several regimens have been described previously for the treatment of EPM.[44,106,123,124] EPM has been described as successfully treated in 55% to 60% of the cases.[123] In the proceedings of the American Association of Equine Practitioners in 1994, 101 cases of EPM were diagnosed by clinical signs, Western blot analysis, and 22 postmortem examinations. One could speculate that the 79 (approximately 78%) that did not die responded to therapy. Treatment has included the combination of potentiated sulfonamides (trimethoprim-sulfas) and pyrimethamine. This combination causes a sequential blockade of folate metabolism in apicomplexan protozoa. The synergistic effect of this drug combination against *Toxoplasma* in other animal species suggested this therapy.[9,125] Many veterinarians at that time recommended a dosage of pyrimethamine of 0.25 to 0.5 mg/kg orally b.i.d. for 3 days, followed by the same dose once a day[123,124] or 0.25 mg/kg body mass orally s.i.d.[44] That dose was found not to be adequate. Based on a recent pharmacokinetic study of pyrimethamine in horses, the 611
dose required to reach the minimum inhibitory concentration for *T. gondii* in CSF is 1.0 mg/kg.[54,126] The 612
success rate of treated cases appears to be greater than 60% to 75%, with no complaints of anemia or thrombocytopenia.

Still others recommend pyrimethamine at a dose of 1 to 2 mg/kg s.i.d. for 90 to 120 days; however, the increased dosage for the full term may result in anemia. Previous work using the 1-mg/kg dose of pyrimethamine once a day did not result in anemia, but that dose was only administered for 10 days.[126] Because of the synergistic effect of the pyrimethamine–trimethoprim-sulfa combination on the parasites, perhaps the dose of pyrimethamine could be reduced and subsequently the incidence of anemia lowered. The trimethoprim-sulfa combinations have been recommended previously at a dose of 15 to 20 mg/kg orally b.i.d. or 15 mg/kg orally t.i.d.[44,123,124] The authors recommend sulfadiazine at a dose of 20 mg/kg orally s.i.d. for the full treatment period. Most of the treatments are administered for at least 5 months but must be extended sometimes. The activity of pyrimethamine, trimethoprim, sulfonamides, and combinations of the medications were tested against *S. neurona* merozoites in tissue culture. Pyrimethamine was demonstrated to be coccidiocidal at 1.0 μg/ml. Trimethoprim was coccidiocidal at 5.0 μg/ml; however, none of the sulfonamides alone had activity at concentrations up to 100 μg/ml. Sulfonamides at 5.0 or 10.0 μg/ml were used with pyrimethamine at 0.1 μg/ml. Activity against *S. neurona* improved.[127] These findings are based on in vitro studies, and further work is needed in controlled clinical trials in horses. Following completion of initial therapy, some clinicians recommend periodic treatments during periods of stress. Other therapies, such as once every 2 to 4 weeks or the first week of every month, also have been used.[44,124] However, careful controlled studies to determine the efficacy of these strategies have not been performed. Periodic treatment may lead to parasite resistance in that particular horse, resulting in the need for ever increasing doses.

Triazine derivative drugs used to prevent coccidiosis in other species in other countries have been used to treat EPM. These drugs (diclazuril and toltrazuril) originally were designed for use as herbicides. The response to therapy in horses with EPM was slightly better than the response documented for the standard therapy based on horses that previously had been treated with the standard therapy.[128] Recently, the pharmacokinetics of diclazuril and toltrazuril have been demonstrated in horses.[129] Currently, diclazuril is only available as a ration premix; therefore large volumes have to be given daily and its present form is not palatable. One advantage to using these compounds is an appreciably shorter duration of therapy, for most treatment regimens are approximately 30 days. One administers diclazuril at the rate of 5 mg/kg for a minimum of 28 days and may repeat it if necessary.

[130] Recent in vitro testing for activity of diclazuril against *S. neurona* has been demonstrated in the laboratory.[131] One may have to administer diclazuril by nasogastric tube daily because some horses refuse to eat the medication. Another anticoccidial drug, toltrazuril, has become popular because of its ease of use and good absorption orally in horses. Toxicity studies of toltrazuril in horses at 50 mg/kg for 10 days resulted in mild anorexia and depression; however, no serious side effects were observed. The current recommended dose is 5 to 10 mg/kg for a minimum of 28 days. More recently, a metabolite of toltrazuril called ponazuril (Marquis, Bayer Corporation, Kansas City, Missouri) has been approved by the Food and Drug Administration for use in treating EPM. One administers Marquis at the rate of 5 mg/kg for 28 days. No side effects have been reported. Nitazoxanide, another novel treatment, recently has been used to treat EPM. Nitazoxanide is a 5-nitrothiazole with a broad spectrum of activity against bacterial, protozoal, and helminth parasites and has been shown to kill *S. neurona* in cell culture. Toxicity studies were performed in horses. When horses were given 2 times the recommended dose, they became lethargic after 1 week of daily dosing; however, when horses were given nitazoxanide at 4 times the recommended dose, they became significantly ill with one death. The suggested dose schedule is 25 mg/kg once daily for the first week and 50 mg/kg once daily for the next 23 days.[130] Field trials currently are under way to gain Food and Drug Administration approval for diclazuril and nitazoxanide.

The prognosis for horses diagnosed with EPM appears to be similar regardless of the treatment used, because most reports suggest an approximate improvement rate of 60% to 75% with the standard therapy.[132–135] However, earlier work suggested the success rate of therapy was about 50%.[124] Some have suggested that less than 25% of affected horses may return to their original function; however, little objective information is available regarding this issue.[133] A recent study with diclazuril resulted in approximately 75% improvement among severely affected horses and approximately 30% (11 of 36) returned to their original level of performance or actually improved beyond the level of performance before illness.[128] An efficacy study of 70 horses given nitazoxanide found that 63% of the horses met the criteria for success after treatment by improving one grade in their neurologic signs.[130] A growing concern is the percentage of horses that have a relapse in clinical disease after cessation of therapy, for some horses relapse days, weeks, or even months after cessation of therapy. The mechanism of relapse is unknown but may be caused by recrudescence of a truly latent stage of the parasite, presence of a small persistent focus of infection, or perhaps re-exposure to the parasite.[54] Anecdotal estimates of 612
the relapse rates after standard therapy range from 10% to 28% of treated horses.[132–135] The relapse rate reported 613
using diclazuril to treat EPM was less than 5%.[128] Some apicomplexans have latent stages, most notably *Toxoplasma* pseudocysts and *Plasmodium* hypnozoites. *Sarcocystis* species are not known to form pseudocysts or hypnozoites. However, *S. faculata* encephalitis in birds may persist for several months without reinfection. This phenomenon simply may represent a low-level infection and not the development of a true latent parasitic stage. *Eimeria tenella* has been shown to develop latent stages in leukocytes, which reactivate after stress. A great deal concerning the life cycle of coccidia remains unknown. The ability to produce experimental infections helps determine whether *S. neurona* forms a latent stage or maintains a persistent, low-level focus of infection. Reinfection also may be responsible in some cases. The efficacy of preventive therapies is open to debate.

Antiinflammatory medications are recommended when acute onset results in dramatic and progressive clinical signs.[44,123,124] The use of flunixin meglumine or phenylbutazone may be helpful. The usual dose of flunixin meglumine is 1.1 mg/kg b.i.d. parenterally; intravenous administration of medical-grade dimethyl sulfoxide (Domoso, Syntex Animal Health, West Des Moines, Iowa) at a dose of 1.0 ml/kg (approximately 1 g/kg) in a 10% solution once daily for 3 days in a row; and although not uniformly recommended, some clinicians use dexamethasone parenterally in severely affected horses at a dose rate of 0.05 mg/kg b.i.d. or sometimes empirically at 50 mg b.i.d.[44,124] However, the authors believe one should use corticosteroids judiciously. The

exacerbation of signs in stressed patients and reports of horses with EPM showing a worsening of signs following the use of these medications suggest one should avoid immunosuppression.[40,106] Ancillary treatments may include padded helmets, slings, good supportive care, and a deeply bedded stall.

Because of the suspicion that protozoal infections occur more commonly in immunocompromised patients, immunomodulators or other therapies that may have a nonspecific enhancement of the immune system may be helpful. One clinician includes levamisole as part of the treatment regimen for her cases of EPM. Studies have shown that levamisole is a nonspecific immunomodulator that affects T cell–mediated immunity, including delayed-type hypersensitivity, and increases the phagocytic activity of macrophages.[136,137] Reaction to other *Sarcocystis* species in domestic animals includes delayed-type hypersensitivity with mononuclear cell infiltration.[3] The use of immunomodulators may have merit, but further investigation is necessary. Although unlikely, these drugs possibly also may enhance the immunopathologic effects associated with CNS infection.

One should monitor prolonged therapy with antifolate medications for signs of bone marrow suppression with resultant anemia, thrombocytopenia, or neutropenia.[44,124] The combination of trimethoprim-sulfamethoxazole and pyrimethamine also has an effect on reproductive function in pony stallions. The drug combination does not appear to affect semen quality, testicular volume, sperm production efficiency, erection, or libido of healthy stallions; however, it may induce changes in copulatory form and agility and alter the pattern and strength of ejaculation.[138] Therefore one should use caution when treating stallions with this combination for neurologic disease believed to be EPM.

Supplementation with folic acid, folinic acid, or brewer's yeast has been recommended for treatment of presumed folic acid deficiency in horses treated with the standard therapy, particularly pregnant mares.[6,124] However, some investigators have discouraged folic acid supplementation because of poor absorption and the potential for toxic effects on the bone marrow.[133] Toxicity has been reported in newborn foals born to mares that were treated for EPM. These mares had been treated with antifolate medications and concurrently supplemented with folic acid. The foals showed evidence of bone marrow aplasia and hypoplasia, renal nephrosis or hypoplasia, and skin lesions similar to the lesions seen in other species.[139] The cause-and-effect relationship between folic acid supplementation and these developmental abnormalities has not been demonstrated conclusively at the present time. However, particularly in pregnant mares, one should not use folic acid supplementation until controlled clinical trials can be performed to corroborate or refute these findings.

Some clinicians recommend the use of additional supplements such as vitamin E and thiamine that may facilitate healing of nervous tissue when treating horses with EPM.[133,134] However, clinical trials have not been performed to establish the efficacy of this supplementation.

10.10.9 Prevention

Because of the nature of the horse business, prevention of clinical cases of EPM will be difficult. Another complicating factor is the widespread distribution of the parasite throughout many parts of the United States. Although a vaccine is currently available, it remains unproven. In light of the difficulties experienced in the development of effective vaccines for other protozoan parasites, development of an efficacious vaccine for EPM most likely will be in the distant future.[140–143] Monitoring high-risk age groups such as young horses and old horses closely for evidence of neurologic disease may help detect EPM early. That EPM may be the cause of the clinical signs when horses are presented for neurologic disease in the warmer months should raise the index of suspicion. Because many major horse competitions take place in the fall of the year, monitoring of horses before 613 614

transport and competition may be helpful. Wildlife such as opossums and pests such as mice and rats should be denied access to feed by using rodent-proof containers to help prevent some cases of EPM. One also should protect forages from wildlife access by storage in enclosed facilities. Excluding birds from facilities may help prevent some cases of EPM, although the role birds may play in the pathogenesis of EPM is not certain. Sporocyst ingestion in birds may result in passage through the intestinal tract and infectivity for other species.[52,86] Case histories from affected horses indicate that the development of clinical signs often follows some other health event, and that has been borne out by a controlled investigation.[42] Close monitoring of broodmares close to foaling and horses that develop a major illness or injury is important, for it may help early diagnosis of EPM cases.

In addition to designing a prevention plan that minimizes risk factors associated with the definitive host, considering the role of the intermediate host in EPM is also important. As was mentioned previously, several species of mammals have been reported to act as natural or laboratory intermediate hosts in the life cycle of *S. neurona*.[68–71] These animals only represent a threat after death. Therefore veterinarians should encourage horse owners to pick up dead cats, armadillos, skunks, and raccoons on their property and dispose of the carcasses so the opossums cannot eat them and excrete more sporocysts. One should retrieve carcasses carefully with an inverted plastic garbage bag or something similar.

10.11—Equine Herpesvirus 1 Myeloencephalopathy

W. David Wilson

Nicola Pusterla

Equine herpesvirus 1 (EHV1) is an economically important pathogen of horses and exerts its major effect by inducing abortion storms or sporadic abortions in pregnant mares, early neonatal death in foals, and respiratory disease in young horses.[1–3] Myeloencephalopathy is an uncommon manifestation of EHV1 infection but can cause devastating losses during outbreaks on individual farms or boarding stables.[4,5] Although EHV4 rarely causes clinical manifestations of disease in organs other than the respiratory tract, isolated cases of myeloencephalopathy and sporadic abortions have been reported in EHV4 infections.[1–3,6,7] Clinical signs of neurologic disease reflect a diffuse multifocal myeloencephalopathy following vasculitis, hemorrhage, thrombosis, and ischemic neuronal injury. Sudden onset and early stabilization of signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates are typical features, although considerable variation exists between outbreaks concerning epidemiologic and clinical findings.[8] Prevention is difficult because many asymptomatic horses are infected latently with EHV1, and vaccines do not confer protection against neurologic manifestations of infection.

10.11.1 Virologic Findings

Of the five distinct herpesviruses that are known to infect horses, three are typical α-herpesviruses with a double-stranded DNA genome and are designated equine herpesvirus 1 (EHV1; equine abortion virus, formerly known as EHV1, subtype 1), EHV4 (equine rhinopneumonitis virus, formerly known as EHV1, subtype 2), and EHV3 (equine coital exanthema virus), and two are γ-herpesviruses, designated EHV2 (formerly called equine cytomegalovirus) and EHV5.[2,3,9–11] In addition, three asinine α-herpesviruses (AHV1, AHV2, and AHV3) have been isolated from donkeys, and of these, AHV3 has been shown by many criteria to be related closely to EHV1. Indeed, EHV1 and AHV3 are related more closely to each other than either is to EHV4.[2,11–13] Phylogenetic analysis and epidemiologic evidence suggest that EHV1 recently has been derived from AHV3, and that donkeys may remain an alternate host for EHV1, serving as a reservoir to infect horses.[9,11] 617

618

EHV1 and EHV4 are distinguishable from EHV2, EHV3, and EHV5 by biologic properties and virus neutralization tests and from each other by restriction endonuclease fingerprinting of DNA, DNA sequences, and several immunologic tests based on monoclonal antibodies to each virus.[1–3,9,10,14] EHV1 and EHV4 produce eosinophilic intranuclear inclusion bodies in infected cells in vivo and in vitro. Several strains have been identified within EHV4 and EHV1, although the epidemiologic, immunologic, and pathogenic significance of this finding is not known. The 1-p and 1-b subtypes of EHV1 likely are capable of inducing neurologic disease. Apart from differences in endotheliotropism, genetic and antigenic fingerprinting and experiments in baby mice have not yielded clear markers distinguishing EHV1 strains that induce neurologic disease or abortion or both.[9,15–19] Recently, a hamster model has been described showing some potential for discrimination between abortigenic and neuropathogenic EHV1 strains.[20]

10.11.2 Epidemiology and Immunity

EHV1 and EHV4 are enzootic in most horse populations, and the majority of horses show serologic evidence of exposure to these viruses. Most horses become infected via the respiratory tract with EHV1 or EHV4 (or both) during the first year of life. After an incubation period of 2 to 10 days, clinical signs of respiratory disease of variable severity develop and resolve within 1 to 2 weeks in uncomplicated cases.[1–3] Resolution of clinical signs is coincident with development of virus-specific neutralizing antibody directed primarily against surface viral glycoproteins. The development of cell-mediated responses is probably critical for recovery.[21] Resistance to reinfection with homologous virus is demonstrable after recovery but generally persists for only 3 to 4 months. Subsequent infections typically induce milder clinical signs or subclinical infection, although virus shedding from the nasopharynx occurs.[1,2] The immune response frequently is not successful in clearing herpesviral infection, and the majority of clinically recovered horses remain latently (asymptomatically) infected with EHV1 or EHV4 (or both) for life.[1,2,22,23] Recently, EHV1 has been shown to evade the host immune system by downregulating major histocompatibility complex class I expression at the cell surface. This process may be a prerequisite to the establishment of latency.[24]

Recrudescence of latent infection is important in the epidemiology of EHV1 and EHV4 and explains why these diseases can occur in closed populations without the introduction of new horses.[1,2,23,25] Signs of EHV1 infection may occur in the horse in which stress-associated recrudescence of infection has occurred, or the horse may remain asymptomatic but shed infectious virus in nasal secretions to infect other horses. Natural infection with EHV1 occurs by inhalation or ingestion of aerosolized infective virus or by direct contact with virus shed in the

products of abortion or in the nasal and ocular discharges and saliva of horses with overt clinical disease, subclinically infected horses, or shedding carrier horses.[1,2,14] Infectious EHV1 virus was detected in the feces of experimentally infected foals that developed diarrhea, suggesting that fecal spread is a possibility.[26] Virus may be shed by clinically affected and inapparently infected horses for 3 weeks or more, and EHV1 may remain infective in the environment for up to 14 days and on horse hair for 35 to 42 days.[2,27,28]

The first definitive association between EHV1 and myeloencephalopathy was made in 1966 in Norway with the isolation of the virus from the brain and spinal cord of a horse that showed signs of severe neurologic dysfunction.[29] The myeloencephalopathic form of EHV1 infection now is considered to have a worldwide distribution, having been recognized in Denmark, The Netherlands, Germany, Sweden, Austria, Britain, Ireland, Australia, India, the United States, and Canada.[4,5,8,18,30–52] In view of the ubiquitous occurrence of EHV1 infection in horse populations, outbreaks of EHV1 myeloencephalopathy are rare. In many instances, cases of neurologic EHV1 infection occur in association with outbreaks of abortion or respiratory disease, although some outbreaks occur in the absence of other manifestations of EHV1 infection and without the introduction of new horses into the group.[14,25,53,54]

The myeloencephalopathic form of EHV1 infection may occur as sporadic individual cases or, more often, as outbreaks involving multiple individuals over a period of several weeks on one or more premises within a limited geographic region[*] Secondary or tertiary waves of clinical disease may occur as previously unexposed horses become infected from a common source over short period.[5,14,35,51] Morbidity rates ranging from less than 1% to almost 90% of exposed individuals and mortality rates ranging from 0.5% to 40% of in-contact horses have been reported[†]Neurologic EHV1 infection can occur at any time of year but the highest incidence is in the late winter, spring, and early summer, perhaps reflecting the seasonal occurrence of abortigenic EHV1 infections during the same months.[43]

The neurologic form of EHV1 infection has been observed in pregnant mares, barren mares, geldings, stallions, and foals, although foals frequently do not show neurologic manifestations of infection during outbreaks that 618
involve severe neurologic disease in adult horses.[4,35] Pregnant mares and mares nursing foals appear be at 619
increased risk for developing neurologic manifestations of EHV1 infection, and the stage of gestation may be important in determining the outcome of infection in pregnant mares.[4,34,35,41,42] Mares infected during the first two trimesters of gestation appear to be more likely to develop neurologic signs without abortion, whereas mares infected during the last trimester are more likely to abort without showing neurologic signs.[14,32,34,42,49]

All breeds of horses are susceptible to the neurologic form of EHV1 infection, and other Equidae also may be affected. EHV1 was the suspected cause of myeloencephalopathy that developed in a zebra 1 week after an in-contact onager *(Equus hemionu onager)* aborted an EHV1 infected fetus.[57] The authors are unaware of reports of neurologic EHV1 affecting donkeys and mules, although donkeys and mules have shown seroconversion indicating infection with EHV1 while in contact with affected horses during outbreaks.[47,48,55] Indeed, donkeys and mules returning from a show were thought to be responsible for dissemination of EHV1 and propagation of multiple outbreaks of neurologic EHV1 infection in Southern California in 1984 and in several subsequent years, suggesting that a donkey-adapted variant of EHV1 with an increased neuropathogenicity for horses may have been involved.[55]

A modified live EHV1 vaccine of monkey cell line origin was shown to be associated with neurologic disease in 486 of 60,000 recipients, prompting its withdrawal from the U.S. market in 1977.[44] No reports of EHV1

myeloencephalopathy were associated with recent use of the modified live vaccine currently approved for use in horses in the United States.

10.11.3 Pathogenicity and Pathogenesis

Natural infection with EHV1 occurs by inhalation or ingestion, after which the virus attaches to and rapidly replicates in cells of the nasopharyngeal epithelium and associated lymphoreticular tissues, causing necrosis, exudation, and infiltration of phagocytic cells. Bronchial and pulmonary tissues also become infected, particularly in foals, thus predisposing them to secondary bacterial pneumonia.[1,2,14,21,58] Migration of virus-infected phagocytes into the circulation results in viremia associated with mononuclear cells (primarily T lymphocytes) of the buffy coat.[1,2,14,59] The immunologically privileged intracellular location of the virus appears to protect it from inactivation by circulating antibody and permits dissemination to other tissues, including the central nervous system (CNS), even in the presence of high levels of antibody.[60] EHV1 is capable of spreading directly from one infected cell to contiguous cells without an extracellular phase.[14] Vascular endothelium is the initial site of infection in the central nervous system and appears to be the predilection site for replication of EHV1 after transfer of the virus from circulating leukocytes.[42,61,62] Viremia, which may be of prolonged duration, can occur during primary and all successive infections with EHV1, even when no clinical signs are apparent; thus all EHV1 infections pose a threat of inducing neurologic disease or abortion.[1,4]

The acute onset of clinical signs of EHV1 myeloencephalopathy appears to result from vasculitis and thrombosis of arterioles in the brain and especially the spinal cord. This causes functional impairment of blood flow and metabolic exchange and, in severe cases, hypoxic degeneration and necrosis (malacia) with hemorrhage into adjacent neural tissues of the white and, to a lesser extent, gray matter[*] This proposed pathogenesis, based primarily on interpretation of the prominent vasculitis seen histopathologically in infected horses and the lack of definitive evidence of viral multiplication in neural tissues, contrasts greatly with the well-established pathogenesis of encephalitis caused by herpesviruses in other species.[9] The propensity of certain EHV1 isolates to induce myeloencephalopathy does not appear to reflect specific neurotropism but rather a significant endotheliotropism[†] The finding of chorioretinopathy and neural lesions in experimentally infected specific pathogen-free ponies, however, suggests that at least some strains of EHV1 may exhibit neurotropism.[64] Furthermore, strong evidence exists that in addition to circulating T lymphocytes, epithelial cells of the respiratory tract, and lymphoid tissues draining the respiratory tract, trigeminal ganglia are important sites for establishing and maintaining the lifelong state of latency that occurs in most, if not all, horses during primary infection with EHV1 and EHV4.[22,23,65–68] The ubiquitous EHV2 has been proposed to play an important role in promoting reactivation of EHV1 and EHV4 from these sites in latently infected horses.[22]

No satisfactory explanation exists as to why some outbreaks of EHV1 infection are associated with a high incidence of neurologic disease, whereas others are not, or why different horses show different clinical manifestations of EHV1 infection during outbreaks.[4,5,36,51] The nature and extent of lesions resulting from EHV1 infection appear to be influenced by the age, sex, reproductive status (including stage of pregnancy), and immune status of the horse; the magnitude of challenge; strain variations; and perhaps the route of infection. [4,36,39] In one carefully monitored outbreak of EHV1 infection on a stud farm in England, less than 17% of 619
infected horses developed neurologic manifestations of infection even though almost 60% of the horses on the 620

farm were confirmed to have been infected.[4] Endothelial cell infection and perivascular cuffing within the CNS appeared to be at least as pronounced in foals that died during this outbreak without showing neurologic signs as in profoundly paretic mares with severe CNS lesions; however, parenchymal neural lesions were minimal in the foals.[4,36] A notable finding during this outbreak was that mares and stallions that developed neurologic signs had considerable antibody responses, whereas the majority of foals did not, despite experiencing a prolonged period of viremia.[4]

The majority of EHV1 infections that cause neurologic signs represent reinfection rather than a new infection.[30,33,69] Infection occurs in horses with significant preexisting serum EHV1 antibody titers, affected horses frequently have high titers at the onset of neurologic signs, and those horses that develop the most severe clinical signs are frequently the ones that show the most rapid increase in antibody titer after infection.[4,41,42] In addition, the characteristic vascular lesions in neural tissues of affected horses are typical of type III (Arthus) hypersensitivity reactions, and circulating immune complexes have been demonstrated at the onset of neurologic signs, suggesting that they may result from an immune-complex vasculitis[*] An immune-mediated mechanism is supported further by the difficulty experienced in isolating the virus from neural tissues of affected horses.[36,52,53] In addition, assessment of risk factors during outbreaks of neurologic EHV1 infection in Southern California in 1984 revealed that horses vaccinated with killed or modified live EHV1 vaccine within the previous year were significantly (9 to 14 times) more likely to develop neurologic manifestations of infection than were nonvaccinated horses.[55]

The finding of circulating antibodies to the neuritogenic myelin protein P2 in the serum of horses that died from EHV1 myeloencephalopathy but not in horses that recovered has led to the suggestion that an alternate immune-mediated mechanism may play a role in the pathogenesis of neurologic EHV1.[70] The presence of this antibody, however, may represent a response to leakage of the protein after damage induced by another mechanism.

Despite the foregoing observations, evidence for an immune-mediated pathogenesis for EHV1 myeloencephalopathy is by no means conclusive. In experimental EHV1 infections in which the onset of neurologic signs 8 to 9 days after infection correlated with a peak in the level of circulating immune complexes, vasculitis was not present in vessels in which endothelial cells did not support viral replication or in organs such as the kidney that one would expect to trap circulating immune complexes.[61] The finding of greatly depressed platelet counts several days before the onset of clinical signs, presumably the result of consumption in thrombi following endothelial damage, suggests that the neuropathologic changes are initiated before circulating immune complexes peak and that the action of immune complexes may be secondary and localized. Failure to isolate the virus from the CNS may be attributable to high levels of circulating antibody and to the endotheliotropism of the virus.[61]

10.11.4 Clinical Signs

In natural and experimental infections, neurologic signs appear 6 to 10 days after infection by the intranasal route[*] The onset of neurologic signs may be preceded or accompanied by signs of upper respiratory disease, fever, inappetence, or hindlimb edema within the previous 2 weeks although in many instances no antecedent signs are notable unless one routinely monitors rectal temperature. However, frequently one finds a herd or

stable history of current or recent cases of respiratory tract infection, fever, inappetence, distal limb edema, abortion, neonatal death, foal diarrhea, or neurologic disease, and for one to encounter different signs of EHV1 infection in different groups of horses on a particular farm is not unusual.[4]

Affected horses are occasionally febrile at the onset of neurologic disease, although most are normothermic and some are hypothermic. Neurologic signs are generally of acute or peracute onset, after which they tend to stabilize rapidly and generally do not progress after the first 1 or 2 days.[30,34,35,43,71] Clinical signs vary depending on the location and severity of lesions, but in most horses, signs reflect predominant involvement of the spinal white matter.[43] Ataxia and paresis of the limbs are the most common signs, with hypotonia of the tail and anus, tail elevation, and urinary incontinence being common but not invariable findings[†] Clinical signs are usually bilaterally symmetric or only mildly asymmetric, although hemiparesis or sudden onset of unilateral hind- or forelimb lameness progressing to unilateral or more generalized ataxia, paresis, and recumbency have been reported.[43,45,46,63,73] Lesions in peripheral nerves and spinal cord were observed in some of these cases.[45] The hindlimbs generally are affected more severely and earlier in the disease course than the forelimbs. In mildly affected horses, transient ataxia and stiffness of the pelvic limbs or dribbling of urine following overflow from a 620

621 distended atonic bladder may be the only signs noted.[34,43] One may note conscious proprioceptive deficits in these cases as reluctance to move, clumsiness, toe dragging, knuckling, stumbling, pivoting, and circumduction in one or more limbs on circling, with spasticity evident in some cases.[35,43,74] These signs are often subtle and may go unnoticed. More severely affected horses show profound limb weakness and swaying of the hindquarters, and a small proportion show complete paralysis of affected limbs, manifested as paraplegia and sitting like a dog, complete recumbency, or tetraplegia.[4,14,43,74]

Distention of the urinary bladder is common and may cause signs of colic or dribbling of urine, which frequently results in scalding of the perineum, legs, and other areas.[48] Cystitis is a frequent complication, particularly when repeated catheterization is necessary to relieve bladder distention.[71] Affected stallions and geldings may develop penile flaccidity and paraphimosis or repeated erections, whereas mare may develop vulvar flaccidity[*]In addition, stallions may experience reduced libido and swelling of the testes.[4,36] Scrotal edema may accompany hindlimb edema at the onset of neurologic signs in some cases.[4,34–36,49] Sensory deficits are uncommon, but perineal hypalgia or analgesia has been noted, and analgesia of the caudal half of the body was observed in one affected horse.[30,34,43,74] Consistent with predominant involvement of the white matter of the spinal cord, flexor reflexes are normal and perineal reflexes are preserved. In recumbent horses, spinal tendon reflexes can be tested and may be increased. Atrophy is rarely seen, even in the later stages of the disease.[43] Affected horses usually remain alert and have a good appetite, even when recumbent, although some show modest depression and inappetence.[35,72] Severe depression, when it occurs, is more often caused by secondary complications than by brain involvement.[72] Unequivocal signs of brain disease are rare, although infarction of the brainstem may cause depressed sensorium, altered behavior, and cranial nerve damage leading to vestibular signs and to lingual, mandibular, and pharyngeal paresis, which may manifest as dysphagia.[32,50,72,73,75] Strabismus, nystagmus, circling, and head tilt have been observed on occasion.[8,32,43,74]

Affected horses show variable progression of clinical signs. Those horses that are affected mildly frequently stabilize rapidly over a period of hours to a few days as edema and hemorrhage resolve and generally recover completely over a period of days to several weeks.[4,5,30,35,51] If recumbency occurs, it generally does so during the first 24 hours, with some horses showing such complete motor paralysis that they are unable to lift their

heads.[45] Severely affected horses may show progression of signs during the first few days and may die in coma or convulsion or be euthanized because of secondary complications.[4]

* References 4, 14, 30, 35, 72, 74.

10.11.5 Laboratory Findings

Cerebrospinal fluid (CSF) analysis typically, although by no means always, reveals xanthochromia, an increased protein concentration (100 to 500 mg/dl), and increased albumin quotient (ratio of CSF to serum albumin concentration), reflecting vasculitis and protein leakage into CSF. The white blood cell count in CSF is usually normal (0 to 5 cells/μl) but occasionally is increased[*] Abnormalities in CSF are not present at the onset of clinical signs in some horses, and changes resolve rather quickly; thus the CSF may be normal within 2 weeks of onset of clinical signs.[42,43,71]

The presence of antibodies to EHV1 in the CSF of affected horses strongly suggests a diagnosis of EHV1 myeloencephalopathy, although such antibodies are absent in many cases.[8,32,42,43,78] One should take into account the albumin concentration, IgG concentration, and EHV1 antibody titer in serum and CSF when interpreting positive antibody titers in CSF.[76] Because the albumin quotient usually is elevated in affected horses and the IgG index is normal, the presence of EHV1 antibodies in CSF reflects leakage of protein across a damaged blood-brain or blood-CSF barrier following vasculitis rather than intrathecal antibody production.[70,76,78] Antibodies therefore are more likely to be present in the CSF of affected horses with concomitantly high serum titers.[42,43,70,76,78] Blood contamination during collection of CSF and other diseases that cause an increase in the permeability of the blood-brain barrier or bleeding into the subarachnoid space may elevate CSF antibody titers falsely if serum titers are also high. Isolation of EHV1 from the CSF of affected horses would confirm a diagnosis but is rarely successful.[43,48]

Virus isolation and identification of EHV1 from nasopharyngeal swabs or buffy coat samples strongly supports a diagnosis of EHV1 myeloencephalopathy in a horse with compatible clinical signs and should be attempted by submission of nasopharyngeal swabs in viral transport medium and an uncoagulated blood sample (citrated or heparinized)[†] Results of virus isolation may be negative, however, because the peak of virus shedding usually has passed by the time neurologic signs appear.[79] The likelihood of isolating EHV1 during outbreaks of 621
neurologic disease increases by monitoring in-contact horses and collecting nasal swab and buffy coat samples 622
during the prodromal febrile phase before neurologic signs develop.[35] Even so, interpretation of positive culture results can be confusing because EHV1 and EHV4 have been isolated from the respiratory tract of normal horses.[27] Application of new diagnostic methods such as polymerase chain reaction (PCR), in situ hybridization, antigen-capture enzyme-linked immunosorbent assay (ELISA), and dot immunobinding to nasal swabs or scrapings, buffy coat samples, or pathologic specimens have improved the speed and specificity greatly with which one can diagnose EHV1 infection.[80–88] Many conventional PCR protocols targeting specific genes of EHV1 have been published in recent years for molecular detection of EHV1 in nasopharyngeal swabs or buffy coat samples.[23,83–87] Although considerable progress has been made in developing PCR protocols for clinical use, quality control of nucleic acid amplification techniques remains an ongoing challenge because of lack of protocol standardization between laboratories.[89] Furthermore, the majority of PCR assays targeting genomic EHV1 DNA are unable to differentiate between a lytic and latent infection. Novel technologies such as the

TaqMan PCR that allow quantitation of viral DNA and detection at the level of gene expression likely will feature prominently as molecular diagnostic approaches to EHV1 infection are refined further in the future.

Serologic testing that demonstrates a fourfold or greater increase in serum antibody titer using serum-neutralizing or complement fixation tests on acute and convalescent samples collected 7 to 21 days apart provides presumptive evidence of infection.[*] Many horses with EHV1 myeloencephalopathy, however, do not show a fourfold rise in serum-neutralizing titer, and some actually show a decline.[48] This may be explained by the finding that when antibody titers rise, they do so rapidly within 6 to 10 days of infection and already may have peaked by the time neurologic signs appear.[†] Although serologic testing has limitations in confirming a diagnosis of EHV1 myeloencephalopathy in an individual horse, testing of paired serum samples from in-contact horses is recommended because a significant proportion of affected and unaffected in-contact horses seroconvert, providing indirect evidence that EHV1 is the causative agent.[‡] Interpretation of the results of serologic tests is complicated by the fact that the serum-neutralizing, complement-fixation, and ELISA tests in use at most diagnostic laboratories do not distinguish between antibodies to EHV1 and EHV4 because of cross-reaction between these viruses. A specific ELISA test based on the C-terminal portion of glycoprotein G of both viruses has been developed and should prove valuable in the investigation and management of disease outbreaks in the future.[91–93]

10.11.6 Diagnosis

The multifocal distribution of lesions results in variability of clinical presentation, which necessitates inclusion of a number of conditions in the differential diagnosis. These conditions include equine protozoal myeloencephalitis, cervical stenotic myelopathy, and cervical vertebral instability (wobbler syndrome), cervical vertebral fracture or other CNS trauma, neuritis of the cauda equina, fibrocartilaginous infarction, aberrant parasite migration, degenerative myelopathy, togaviral encephalitis (flaviviruses and alphaviruses), rabies, botulism, CNS abscess, and a variety of plant and chemical intoxications.[8,43] Sudden onset and early stabilization of neurologic signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates is sufficient to make a tentative diagnosis of EHV1 myeloencephalopathy.[8] Antemortem diagnosis is supported further by ruling out other conditions; demonstrating xanthochromia and elevated protein concentration in CSF; identifying EHV1 in or isolating EHV1 from the respiratory tract, buffy coat, or CSF; and demonstrating a fourfold increase in antibodies using serum-neutralizing, complement fixation, or ELISA tests performed on acute and convalescent serum samples collected from affected or in-contact horses 7 to 21 days apart.[5,51,94] Antemortem confirmation of a diagnosis of EHV1 myeloencephalopathy is frequently not possible, however, particularly when an individual horse is affected, because the foregoing tests do not yield consistent results in all cases.

10.11.7 Treatment and Prognosis

Because EHV1 is a contagious and potentially devastating infection, horses suspected of being affected should be isolated promptly and strictly until EHV1 is ruled out by confirmation of an alternate diagnosis.[72] No specific treatment is available; thus management of horses with EHV1 myeloencephalopathy aims toward supportive nursing and nutritional care and reduction of CNS inflammation.[8] One should encourage horses that are not recumbent to remain standing and should protect them from self-inflicted trauma by the provision of good footing, such as a grass paddock; by placement of food and water in an accessible location at a convenient height 622 above ground level; and by other measures, including the use of padded hoods and elimination of obstacles. One 623 should maintain patients that become recumbent in a sternal position on a thick cushion of dry absorbent bedding and should roll them frequently (at least every 2 to 4 hours) to reduce the risk of myonecrosis and decubital ulcers. Whenever possible, one should lift and support the horse in the standing position using an appropriately fitting sling.[5] Slings are most beneficial for moderately affected horses that are too weak to rise but are able to maintain a standing position with minimal assistance.

Affected horses usually maintain a good appetite, even when recumbent, although hand feeding may be necessary to encourage some horses to eat. Maintenance of hydration is important, and provision of a laxative diet or the administration of laxatives such as bran mashes, mineral oil, or psyllium may be necessary to reduce intestinal impaction. One usually can meet the caloric and water needs of anorectic patients usually by feeding gruels of alfalfa-based or similar pelleted feeds in water or balanced electrolyte solution via nasogastric tube. If oral intake is insufficient to meet the daily water needs of 60 to 80 ml per kg of body mass per day, one can maintain hydration by intravenous administration of balanced electrolyte solutions.[43] One also can use partial or total parenteral nutrition to meet the caloric needs of anorectic, recumbent horses.

If affected horses are unable to stand and posture to urinate or if bladder function is impaired significantly, manual evacuation of the bladder by application of pressure per rectum may be necessary. If these measures are unsuccessful, judicious urinary catheterization is indicated and should be performed aseptically with the collection tubing attached to a sterile closed bag to minimize the risk of inducing urinary tract infection.[8,72,74] Cystitis is, however, a frequent complication, particularly in recumbent horses, and can lead to bladder wall necrosis, bladder rupture, and systemic sepsis. Urine scalding can become a major problem, particularly in mares that dribble urine. Prevention involves regular washing of the perineum, tail, and hindlegs with water, application of water-repellent ointments and braiding or wrapping the tail to simplify cleaning.[8] Administration of enemata or manual emptying of the rectum also may be necessary to promote defecation and improve patient comfort.[8]

Because vasculitis, hemorrhage, and edema are prominent early lesions and may have an immune basis, treatment with corticosteroids early in the disease course is recommended by most clinicians, although no objective data are available to document the efficacy of these or other antiinflammatory drugs.[35,43,72] A short course of treatment with prednisolone acetate (1 to 2 mg/kg/day) or dexamethasone (0.05 to 0.25 mg/kg parenterally twice daily) for 2 to 3 days with decreasing doses over another 1 to 3 days is recommended.[8,43,74] Flunixin meglumine (1.1 mg/kg body mass every 12 hours) is indicated to treat CNS vasculitis. Dimethyl sulfoxide at a dose of 0.5 to 1.0 g/kg administered intravenously as a 10% to 20% solution in normal saline or 5% dextrose once daily for up to 3 days commonly is used to treat horses with suspected CNS trauma or inflammatory disease, such as EHV1.[8] Although the efficacy of dimethyl sulfoxide for treating herpesvirus myeloencephalopathy has not been evaluated, its reported ability to inhibit platelet aggregation and scavenge free

radicals support its continued use. Because of the high risk of development of cystitis and other secondary bacterial infections, administering broad-spectrum antibiotics such as potentiated sulfonamides (trimethoprim-sulfamethoxazole 30 mg/kg body mass orally every 12 hours) or ceftiofur (2.2 mg/kg body mass intramuscularly or intravenously every 12 hours) is advisable, particularly when corticosteroid treatment is used.[5,8,43] One should base the choice of antibiotics for treating established secondary bacterial infections of the urinary tract, respiratory tract, or other areas on the results of culture and susceptibility testing.

Acyclovir, a synthetic purine nucleoside analog with inhibitory activity against several human herpesviruses, has been shown to exert an inhibitory effect on EHV1 in vitro.[95] Apparent efficacy of acyclovir was demonstrated by a successful treatment outcome in two of three foals with congenital EHV1 infection.[96] Similarly, four of six severely neurologically affected horses recovered completely, and a fifth horse showed significant improvement when treated with acyclovir during a recently reported outbreak of EHV1 myeloencephalopathy involving 19 horses in a riding stable.[51] Although the aforementioned results are promising, one should interpret them with caution because whether treatment with acyclovir actually influenced the outcome in these cases is not known. In addition, the author and his colleagues at the University of California have not experienced a similarly high rate of success. Data describing the pharmacokinetics, bioavailability, and safety of acyclovir in horses are lacking; therefore dosing protocols have been based on extrapolation from dosage regimens used in human beings to treat infections with herpes simplex virus or varicella zoster viruses. The low bioavailability of orally administered acyclovir in human beings necessitates frequent administration of high doses. Accordingly, acyclovir doses of 8 to 16 mg/kg administered 3 times daily for 7 to 12 days were used to treat congenital EHV1 infection in equine neonates,[96] and doses of 20 mg/kg administered 3 times daily for 5 days were used to treat horses with EHV1 myeloencephalopathy without apparent toxicity.[51] The primary route of elimination of acyclovir is renal, and some human beings with renal failure have developed adverse effects to acyclovir, primarily manifesting as 623

624 neurologic disturbances.[97] Therefore one should monitor and maintain renal function when administering acyclovir. Clearly, additional studies are needed to define the appropriate dose for acyclovir in horses and to document its efficacy for the treatment of EHV1 myeloencephalopathy. Another nucleoside analog, penciclovir, has been shown to have excellent activity against EHV1 in tissue culture and in a mouse model of EHV1 infection.[98]

Affected horses that remain standing have a good prognosis for recovery, and improvement generally is apparent within a few days, although a period of several weeks to more than a year may be required before horses with severe deficits show complete recovery.[*] In these instances, control of urination frequently returns before gait abnormalities resolve completely.[72] Some horses may be left with permanent residual neurologic deficits, including urinary incontinence and ataxia, that may necessitate euthanasia many months beyond onset of neurologic signs.[5,43,47,48] Horses that become recumbent have a greatly increased likelihood of developing complications such as myonecrosis, urinary tract infection, decubital ulcers, respiratory tract infection, gastrointestinal obstruction and ulceration, injuries, and complications of dehydration and malnutrition. Their prognosis for recovery is therefore poor, particularly if they remain recumbent for more than 24 hours and they are unable to stand after being lifted with a sling.[4,5] One should not elect euthanasia prematurely in valuable horses, however, because reports document horses standing again and recovering completely to race successfully after being recumbent for several days to 3 weeks.[35,45,49] Most mildly affected mares return to breeding soundness in the same season, whereas fertility is likely to be compromised in more severely affected mares that experience urinary retention.[4] Recurrence or exacerbation of neurologic signs in horses that have recovered completely has not been documented, even though the majority likely remain latently infected.[14,25,43,72]

10.11.8 Pathologic Findings

When horses with suspected EHV1 myeloencephalopathy die or are euthanized, one should submit the whole carcass or at least the head, spine, spleen, thyroid, and lung for postmortem examination because lesions frequently are not confined to the CNS of horses with EHV1 myeloencephalopathy[†] Gross pathologic lesions in the CNS frequently are not found, but small (2 to 6 mm) focal areas of hemorrhage distributed randomly throughout the meninges and parenchyma of the brain and spinal cord may be observed[*] More diffuse dural hemorrhage is notable in some cases and may extend to spinal nerve roots and the cauda equina.[41,42,53] Small plum-colored areas of degeneration and hemorrhage are sometimes grossly visible in fresh tissue at various levels of the spinal cord (white matter), and malacic foci may be visible macroscopically in the gray and white matter in sliced fixed sections of brain.[41,42,49,50,53]

The gross and histologic lesions in the CNS reflect vasculitis, congestion, and secondary ischemic degeneration of nervous tissue[†] Although vasculitis is a consistent finding, degeneration of nervous tissue is evident chiefly in those horses with clinical signs of severe neurologic disease.[36,41,42] The vasculitis is often severe and has a widespread, random, multifocal distribution, with the most severe lesions usually in the brainstem and spinal cord. In the brain the meningeal and penetrating or radiating vessels in gray matter are the major sites of vascular involvement. Thus foci of axonal swelling and malacia develop in the grey and white matter, particularly adjacent to the meningeal surface and in the deep cortex adjacent to the white matter.[41,42,53] In the spinal cord a similar orientation to meningeal vessels results in degeneration of white matter within ovoid, linear, or wedge-shaped foci affecting predominantly the lateral and the ventral white columns.[42] In some instances, sheaths of nerve roots and nerves and capsules of ganglia also are involved.[36,41,42,53] Trigeminal ganglionitis may be present but usually is not manifest clinically.[45]

Ocular lesions, including uveal vasculitis with perivascular mononuclear cell cuffing in the ciliary body and optic nerve or extensive retinal degeneration, have been observed in foals showing signs of bilateral hypopyon and iritis or severe visual impairment and chorioretinopathy without anterior segment involvement during field and experimental EHV1 infections.[4,36,42,53,64] In some foals EHV1 appears to induce ocular and neural damage in the absence of gross signs of neurologic or visual impairment.[64] During paralytic infections, secondary viral replication occurs in blood vessels of the testis and epididymis in addition to CNS and may be responsible for reported signs of scrotal edema and loss of libido in affected stallions.[4,99]

EHV1 infrequently is isolated from the CNS of affected horses that show typical lesions[‡] Thus one should attempt to isolate the virus from other sites to support the diagnosis. Those sites most likely to yield virus or to contain viral antigen include the turbinates and nasal passages, lymph nodes draining the upper respiratory tract, 624
lung, thyroid, spleen, and endometrium, in addition to the brain.[36,43,90] Immunofluorescent antibody testing of 625
brain and spinal cord sections is considered to be more sensitive than virus isolation, but false-negative results have been observed.[36,43,52] An indirect immunoperoxidase method using orthodox light microscopy was described and was shown to be highly sensitive for identifying individual antigen-containing cells in the CNS and other areas of the body, even at sites containing few or no lesions or inclusion bodies and in which virus could not be detected by immunofluorescent antibody testing or virus isolation.[36] Similarly, the PCR technique has been shown to be more sensitive than virus isolation for detecting viral antigen in nasopharyngeal swabs collected from horses with respiratory tract disease caused by EHV1 or EHV4.[83] Both of these techniques—as

well as antigen-capture ELISA tests, dot immunobinding, and in situ DNA hybridization, which are sensitive and readily differentiate between EHV1 and EHV4—show great promise for routine application to samples collected ante mortem or at necropsy from affected horses.[36,62,81–84,88]

10.11.9 Control and Prevention

Control measures during outbreaks of EHV1 infection aim at reducing spread by infectious aerosols, direct contact, and fomites and at reducing stress-induced recrudescence of latent EHV1 infection.[1,2,14] If neurologic signs or other clinical signs suggestive of EHV1 infection occur, one should isolate affected animals promptly and completely in a well-ventilated airspace separate from the remainder of the herd, and one should isolate in-contact horses in their current location as one or more small groups for at least 1 month and pregnant mares preferably until they foal.[1–4,14,35,75] On breeding farms, one should suspend covering.[4] Aborted fetuses and fetal membranes are rich sources of infectious virus and therefore should be collected at the site they are found and placed in leak-proof containers such as heavy gauge plastic bags for submission for diagnostic evaluation or for disposal by burning.[1,2] Similarly, bedding and dirt contaminated with fetal fluids should be disposed of or burned, and stalls or other areas occupied by infected horses should be cleaned thoroughly, disinfected with an iodophor or a phenolic product, and left empty for several weeks.[14] Equipment used to handle, groom, feed, water, muck out, or transport affected horses also should be cleaned and disinfected or disposed of. Thereafter separate equipment and personnel should be used for affected and unaffected horses, or at least caretakers should handle affected horses last and wear disposable gloves, surgical masks, and protective clothing that can be changed or disinfected between groups.[14] Although control measures are frequently successful in stopping further spread of infection during outbreaks, one should note that transmission of infection before control measures are implemented may result in a secondary waves of disease 1 to 2 weeks later.[4,14,35]

Traffic of horses and human beings on the premises should be minimized, and movement of horses onto and off the infected premises should be suspended until at least 3 weeks after resolution of acute signs in the last clinical case or until tests show that virus transmission is no longer occurring.[1–4,8,14] Collection of nasal swabs and uncoagulated blood (buffy coat) samples from clinically affected and exposed horses within each group and demonstration of stable or declining antibody titers in serum samples proved to be helpful in determining patterns of exposure and spread and in establishing when virus transmission had ceased in one reported outbreak. Protracted viremia lasting several weeks or months occurs in some horses and extends the period during which movement of horses should be restricted.[4]

If horses must enter the farm, they should be current on EHV1 vaccination and should be isolated away from the resident population. Although giving booster vaccinations to exposed pregnant mares during outbreaks of abortigenic EHV1 infection is common practice,[1,2,14] vaccination of exposed horses during outbreaks of EHV1 myeloencephalopathy has not been investigated and cannot be recommended at this time because of the possibility of an immune-mediated pathogenesis. Administering booster doses of inactivated EHV1 vaccine to all unexposed horses that have not been vaccinated within the previous month is common practice, however.

Preventive measures should include routine management practices aimed at reducing the chances of introducing and disseminating infection.[3,14,63,101] New arrivals should be isolated for at least 3 weeks before joining the herd, distinct herd groups should be maintained based on the age and use of horses, and care should be taken to minimize or eliminate commingling of resident horses with visiting or transient horses. In particular, pregnant broodmares should be maintained in groups separate from the remaining farm population. In addition, minimizing stress associated with overcrowding and handling procedures is prudent in an attempt to reduce recrudescence of latent EHV1 infection.[14,25,63,101]

No method is known that reliably prevents the neurologic form of EHV1 infection. None of the EHV1 or EHV4 vaccines currently available carry a claim that they prevent EHV1 myeloencephalopathy, and the disease has been observed in horses vaccinated regularly at 3- to 5-month intervals with inactivated or modified live vaccines.[8,43,48,50,51] Repetitive administration of currently available EHV1 and EHV4 vaccines appears to induce some immunity to respiratory disease and reduce the incidence of abortion but does not block infection 625
and induction of viremia or eliminate the possibility of clinical disease and establishment of the carrier state. 626
[1,2,14,50,101–106] Although the protection induced by inactivated EHV1 vaccines is incomplete and of short duration, the vaccine reduces virus excretion in horses that do become infected.[103,106] To maintain appropriate vaccination procedures in an attempt to reduce the incidence of other manifestations of EHV1 infection and reduce the magnitude of challenge experienced by in-contact horses is logical. This indirectly may help prevent EHV1 myeloencephalopathy.[43] An attenuated live virus vaccine based on the temperature-sensitive and host range mutant clone 147 of EHV1 has been evaluated recently. The novelty of this vaccine lies in the fact that a low dose administered intranasally replicated in conventional target species and conferred exceptional efficacy against respiratory disease, virus shedding, viremia, and abortion caused by a severe EHV1 challenge.[107,108] The intranasal vaccine also claims to protect against less common manifestations of EHV1 infection such as paresis and jaundice (Patel, et al., unpublished).

10.12 10.12—Polyneuritis Equi

William J. Saville

Polyneuritis equi is an uncommon neurologic disease of all equine species that is characterized by tail and anal sphincter paralysis, often accompanied by cranial and peripheral nerve damage.[1–13] Previous reports referred to the disease as neuritis of the cauda equina because of the susceptibility of this region, but frequent involvement of the 628
629 cranial and peripheral nerves led to the term *polyneuritis equi*.[2] Although the disease has been recognized more readily in Europe, where it was first reported by Dexler in 1897, cases have now been reported in Great Britain, Canada, and the United States.[3,4,6,14] The disease does not appear to have a breed, sex, or age predilection, but the youngest horse affected was 17 months of age.[2,5,6,13–15]

The cause of this disease is unknown. Primary immune reaction and viral inflammatory disease have been suggested, although possibly one may be a consequence of the other.[2] Several infectious agents have been suggested, such as equine herpesvirus type 1, equine adenovirus, and streptococcal bacteria.[10,12,16] The pathologic lesions resemble those of Guillain-Barré syndrome in human beings, and the disease is also similar to experimental allergic neuritis in rats.[10,13] Evidence suggests that the immune system is involved because horses with polyneuritis equi have circulating antibodies to P2 myelin protein, which is present in rats with experimental allergic neuritis.[10,17] The significance of this is that polyneuritis equi may be an inflammatory and an immune-mediated disease.

10.12.1 Clinical Signs

The disease often manifests itself in two forms: (1) the acute signs include hyperesthesia of the perineal or head region or both, and (2) in the chronic form, horses show paralysis of the tail, anus, rectum, and bladder. Paralysis often is accompanied by fecal and urinary retention, urinary scalding of the hindlimbs, and in male horses, penile paralysis[*]

The hindlimb signs in affected horses are often symmetric, whereas the head signs are often asymmetric.[6,13,15] Muscle atrophy in the gluteal region is sometimes present along with mild degrees of ataxia.[2,3,5,6,9] Muscle atrophy associated with cranial nerve involvement may occur in the head region. Damage to peripheral motor nerves may result in gait deficits and abnormal use of forelimbs or hindlimbs.[1,12,13,15]

Although cranial nerve involvement is reported primarily to affect cranial nerves V, VII, and VIII, any of cranial nerves II, III, IV, VI, IX, X, and XII also may be involved.[2,4,5,8,13] The horses may have trouble with mastication and swallowing.[12] A head tilt, ear droop, lip droop, and ptosis are common signs.[8,12,13] One report describes a horse with brachial neuritis along with involvement of cranial nerves V, VII, and XII. The horse also exhibited mild ataxia and weakness in all limbs. The horse performed the hopping test poorly on the right thoracic limb, and the horse resented palpation in the right caudal cervical and prescapular region.[2]

Colic caused by fecal retention may be the primary sign when one initially examines horses with polyneuritis equi. Fecal retention leads to an impaction caused by the flaccid anal sphincter, often accompanied by an atonic, distended bladder.[1] If the clinician sees these signs in the acute or hyperesthetic form, they usually progress to the chronic form of hypalgesia or anesthesia. An area of hyperesthesia may surround the area of anesthesia.[1,2,8]

* References 1–3, 6, 8, 9, 12, 13, 15.

10.12.2 Diagnosis

The definitive diagnostic test is a postmortem examination. The peripheral white blood cell count usually reveals a mature neutrophilia with hyperfibrinogenemia, mild to moderate anemia, and an increased total protein—all indications of a chronic inflammatory process.[3,5,13,15] Examination of the cerebrospinal fluid may reveal an elevated protein (70 to 300 mg/dl) along with an elevated white blood cell count, which indicates a mononuclear inflammatory reaction, although cytologic examination of cerebrospinal fluid may be normal, particularly in the acute stage of the disease[*]

Radiography may be required to rule out trauma to the tail head or cranial nerve involvement such as a fractured petrous temporal bone.[2,8]

Some horses with clinical signs exhibit circulating P2 myelin antibody in the serum.[10,17] However, the presence of this antibody only supports the diagnosis; the same antibody has been detected in horses with equine herpesvirus 1 and equine adenovirus infections[†]

Classically, the primary pathologic lesions involve the extradural nerve roots but also may involve the intradural nerve roots.[2,3,5,12,13] The lesions are granulomatous with various degrees of inflammation and infiltration of lymphocytes, eosinophils, macrophages, giant cells, and plasma cells. This inflammation leads to myelin degeneration, subsequent axonal degeneration, and thickening of the epineurium, endoneurium, and perineurium with proliferation, which causes obliteration of the neural architecture by the fibrous tissue.[1,2,9,13] The most severe lesions are in the cauda equina, but swelling, edema, and hemorrhage of cranial nerves may occur. The fibrous tissue formation may lead to adhesions between the meninges and the periosteum of the vertebral bodies.[13] Reports describe involvement of the autonomic nervous system, but no changes in clinical signs have been reported (post mortem only).[2,4]

The polyneuritis lesions are typical of the Guillain-Barré syndrome in human beings, experimental allergic neuritis in rats, and coonhound paralysis in dogs.[2,5,11–13] This similarity may indicate a combination of 629
inflammatory and immune-mediated mechanisms in the pathophysiology of polyneuritis equi. 630

* References 2, 3, 5, 6, 8, 11, 13.

† References 1, 2, 10, 13, 16, 18.

10.12.3 Differential Diagnosis

The most important differential disease is trauma to the sacrococcygeal area of the spinal canal, which can be differentiated by radiography of the area looking for fractures or displacements.[2,6,8]

Equine protozoal myeloencephalitis is the second most common disease in the differential diagnosis of polyneuritis equi. The usual signs of equine protozoal myeloencephalitis include asymmetric damage in the limbs and brain and brainstem lesions causing cranial nerve deficits with alterations in attitude, whereas the cranial nerve deficits of polyneuritis equi are peripheral, with no change in attitude.[6] This disease may be differentiated from polyneuritis equi by Western blot analysis of the cerebrospinal fluid.[19]

Equine herpesvirus (type 1) myeloencephalitis often has an acute onset following an episode of fever, cough, and nasal discharge or following one or more abortions on a farm. This condition often affects more than one horse on a farm. Herpesvirus has a rapid onset and often results in severe hindlimb weakness and ataxia along with bladder dysfunction. Urinary dribbling sometimes may occur. The ataxia and weakness is usually symmetric and may result in recumbency. Occasionally, the horses sit like a dog. Cranial nerve involvement is not common.[20–23]

One should consider verminous myeloencephalitis; the signs vary and depend on the migratory pathway of the parasite. Diffuse or multifocal brain and spinal cord lesions have been reported. The onset is usually sudden with rapid deterioration and death. The incidence of this disease is low, perhaps because of more intense parasite control.[24–26]

One should consider equine motor neuron disease in the differential diagnosis. Horses with motor neuron disease have symmetric muscle wasting or atrophy and weight loss with significant weakness, sweating, and muscle fasciculations. However, these horses are not ataxic and their unique clinical feature is that they walk better than they stand. This disease is a denervation atrophy of type 1 muscle fibers only and may be diagnosed by a spinal accessory nerve biopsy or sacrodorsalis caudalis muscle biopsy.[27]

10.12.4 Treatment

The primary therapy is palliative. No treatment for the disease is known. Removing feces from the rectum and evacuating the bladder are usually necessary. If cystitis caused by bladder distention occurs, systemic antibiotics may be indicated. Some attempts have been made at treating the inflammation with corticosteroids, but the effects have been short lived. The prognosis is usually poor, but the progression of the disease is slow. Some animals may be maintained for many months[*]

10.13

10.13—Togaviral Encephalitis

Joseph J. Bertone

630

631

Togaviridae are small, lipid- and protein-enveloped RNA viruses. Several insect-borne viruses (arboviruses) of the genera *Alphavirus* and *Flavivirus* have been associated with encephalitis in horses. The structure of the viruses and associated clinical presentations are similar among the viruses, but the epizootiology and antigenicity are distinct. *Alphavirus* species (formerly arbovirus group A) tend to be more infectious and more often are associated with epidemics compared with *Flavivirus* species (formerly arbovirus group B). *Flavivirus* species tend to be associated with sporadic outbreaks. In the Togaviridae, equine arteritis virus, a *Rubivirus* species, has been associated with some neurologic deficits and central nervous system edema,[1] which is discussed elsewhere.

In general, birds, rodents, and reptiles act as reservoirs. Mosquitoes often play a role in transmitting the disease among these species. Mosquitoes and, less commonly, other insects feed on sylvatic hosts and subsequently transmit the disease to horses and human beings.

10.13.1

Alphavirus Encephalitides: Eastern, Western, and Venezuelan Equine Encephalomyelitis

The predominant togaviral encephalitides in the Western Hemisphere are associated with eastern (EEE), western (WEE), and Venezuelan (VEE) equine encephalitis (Table 10.13-1).

10.13.1.1

CAUSE

EEE and WEE are specific and discrete togaviral particles. North and South American antigenic variants of EEE exist. WEE variants include eastern, western, and Highlands J strains. The various strains have equivocal differences in antigenic properties and biologic behavior, and extensive geographic overlap occurs.[2] The molecular basis for the antigenic variation between EEE and WEE has been described.[3] VEE virus has four subtypes. Type I variants A, B, and C are associated with disease and epidemics. Type I variants D, E, and F and types II, III, and IV are endemic and usually not associated with clinical disease.[4–7]

10.13.1.2

EPIZOOTIOLOGY

Encephalitis similar to the viral encephalitides has been reported in the United States for many years with high morbidity and mortality rates.[8,9] Evidence that an eastern and western virus exist and are antigenically distinct was first reported in 1933.[10] Horses immunized with strains of virus isolated from infected horses from the East or West were protected differentially when vaccinated with attenuated virus from one location and exposed to virus from the other.[10–12]

10.13.1.2.1 Distribution

In general, disease associated with EEE, WEE, and VEE is restricted to the Western Hemisphere and ranges from temperate to desert climates. Each virus and incidence of associated equine disease has a characteristic distribution. The range of positive serologic tests for the viruses is often far greater than the range of clinical disease[13–39] (Figure 10.13-1). For example, clinical disease associated with VEE was identified in southern Texas in 1971. However, asymptomatic horses with significant titers for VEE (type II) often are identified in Florida where the disease syndrome has not been evident.[16] The WEE virus is recognized in reservoir avian hosts in the eastern United States; however, clinical disease rarely is identified there. Geographic variation in viral virulence may be an explanation. Some importance of the vector in eliciting a more virulent virus lies in the fact that the vector for WEE in the East is *Culiseta melanura,* which is the common vector for EEE. This mosquito may not be able to generate the virulent state of WEE, for clinical disease in that region is rare. Equine disease associated with WEE is rare on the eastern seaboard of the United States but is recognized.[40] Outside the Western Hemisphere, EEE has been identified in the Philippines,[41] and some indications point to its presence in Europe.[42]

10.13.1.2.2 Epidemic

Several requirements must be met for epidemics associated with EEE, WEE, or VEE to develop. Long 631
lapses can occur between outbreaks if all of these conditions are not met. These prerequisites include 632
adequate and adjacent numbers of reservoir animals, sufficient quantities of virulent viruses, infected intermediate hosts, insect vectors, and susceptible horse and human populations.[43,44] Prediction of outbreaks has been attempted but without success,[36,45,46] which indicates that other, unknown factors may exist.

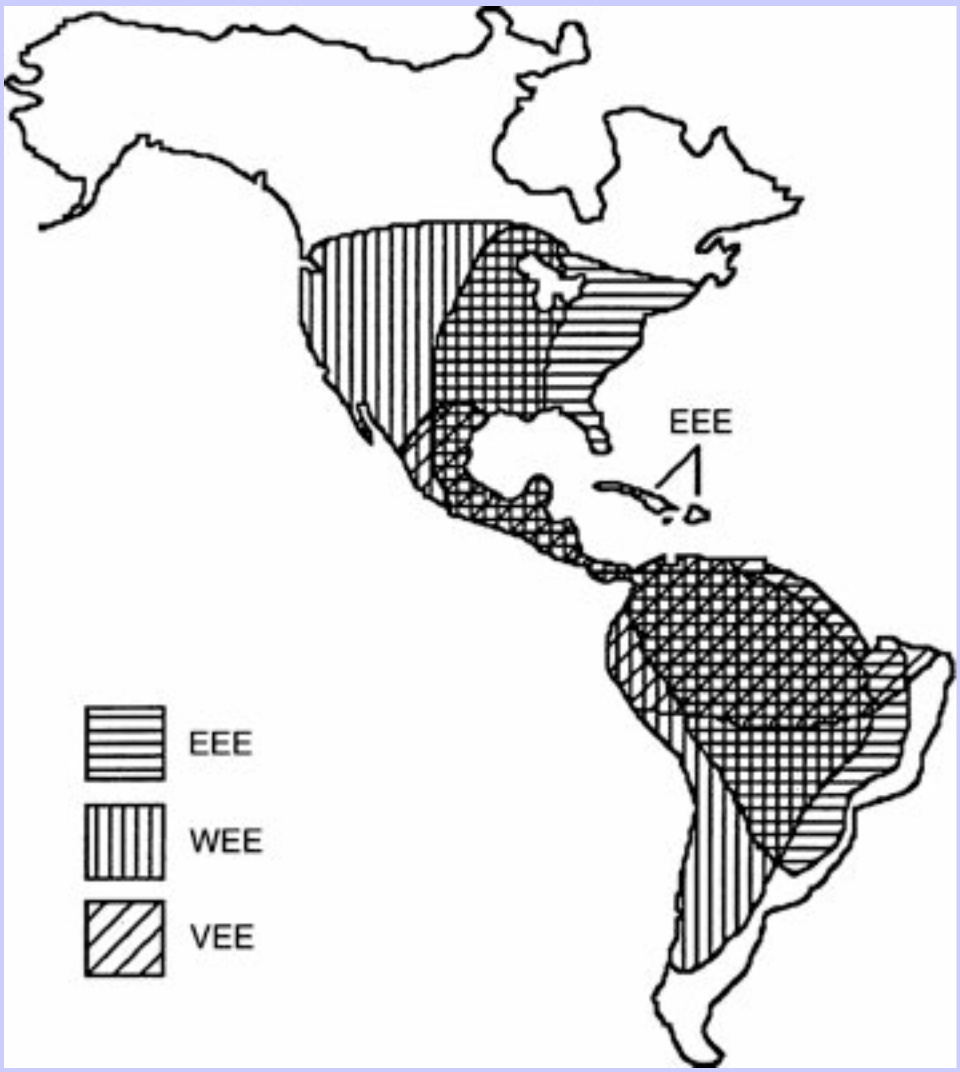
TABLE 10.13-1 A Summary of the Major Togaviral Equine Encephalitides[*]

VIRUS[†]	MAJOR DISEASE VECTOR	ZOONOTIC POTENTIAL	AMPLIFICATION FROM HORSES	DISEASE SPREAD	VIREMIA	EQUINE MORTALITY	HUMAN MORTALITY
EEE	Aedes spp.	Unlikely	Unlikely	Vector	Low	75%-100%	50%-75%
WEE	Culex tarsalis	Unlikely	Unlikely	Vector ±secretions	Low	20%-50%	5%-15%
VEE	Culex melanoconium, Aedes spp. Phosphora spp.	Occurs	Occurs	Vector ±secretions	High	40%-80%	1%

* The statements made are generalizations, and some degree of variation occurs.

† EEE, Eastern equine encephalitis virus; WEE, western equine encephalitis virus; VEE, Venezuelan equine encephalitis virus.

Figure 10.13-1 Predominant distribution of *Alphavirus* spp.–associated equine encephalitis in the Western Hemisphere. This figure represents the disease distribution. Positive serologic results for the diseases are more widespread. *EEE,* Eastern equine encephalitis virus; *WEE,* western equine encephalitis virus; *VEE,* Venezuelan equine encephalitis virus.



10.13.1.2.3

Reservoirs

With minor exceptions, Togaviridae persist by asymptomatically infecting wild animals (sylvatic hosts) such as birds, small mammals, and reptiles by unknown mechanisms.[47] The viruses survive during the winter or nonvector season in sylvatic populations.[46,48]

10.13.1.2.4

Vectors

Specificity of the viruses for particular vectors occurs. Vector distribution explains viral distribution to a large degree. The vectors for EEE include *C. melanura* and *Aedes* species.[13,29,49,50] *C. melanura* for the most part is confined to freshwater swamps, feeds primarily on swamp birds, and rarely is found in areas of increased horse populations.[13] In general, *C. melanura* serves as the vector for the enzootic cycle, which involves swamp birds. *Aedes* species appear to be more important in epizootics and epidemics.

In Florida, WEE persists continuously in *C. melanura* (see the previous discussion).[13] Important WEE vectors include *Culex tarsalis, Dermacentor andersoni,*[51,52] and *Triatoma sanguisuga* (assassin bug).[53,54] The cliff swallow bug *(Oeciacus vicarius)* may be an overwintering reservoir[51,55] (see the following discussion).

The vectors for VEE include *Culex melanoconium,* and *Mansonia, Aedes,* and *Phosphora* species.[16,17,23,24]

10.13.1.2.5

Virulence Induction

Some puzzles exist in light of the ability of some mosquitoes and other insects to carry two or three viruses and the inability of these viruses to induce disease. Some form of virulence induction specific to the viruses may occur. The existence or mechanism of virulent mutation is controversial. The intermediate host may play a key role in this process, but that is speculative.

10.13.1.2.6

Vector Ecology

Vector transmission is the most important way infection spreads. WEE and VEE may spread by nasal secretions, but this is less likely.[16,17,54,56] 632

633

Vectors transmit viral particles between sylvatic hosts when taking a blood meal. If the virus is able to penetrate the gut of the vector, it may pass through the hemolymph to oral glands, multiply, and subsequently be shed in saliva and other oral secretions. If the blood meal contains adequate numbers of viral particles, multiplication may not be required for transmission. In most instances and judiciously assumed, the mosquito remains infected for life.[50,57]

10.13.1.2.7

Seasonal Incidence

In most instances the diseases occur during the height of the vector season. In temperate climates the highest number of cases occurs between June and November. In warm climates, where the vector season is longer, the disease problem lasts longer[*]

10.13.1.2.8
Zoonology

Clinical infection in human beings usually involves old or young persons. Signs, symptoms, and morbidity and mortality rates are virus-specific.[58]

Circulating virus concentrations are often too low for transmission of EEE from infected horses to human beings, mosquitoes, and other animals. Human disease most likely is associated with insect vector contact and often coincides with or is preceded by equine epizootics.[45] In the acute stages of equine disease, a transient, substantial viremia occurs. Therefore if vector density increases, an acutely infected horse could be a transient amplifier of EEE. Spread from horse to horse is possible.[49] Clinical signs in human beings include acute fulminant encephalitis, headache, altered consciousness, and seizures. The mortality rate is 50% to 75%.[58]

Human beings and horses are terminal hosts for WEE. Human cases of WEE occur yearly, but fatality and incomplete recovery are rare. These cases are associated with vector contact. Environmental conditions that decrease exposure to insects decrease the incidence of disease.[59] Increased numbers of animals with clinical equine disease are an indication of heavy sylvatic concentrations of virus and are not a potential source of infection for human beings. Generally, increased numbers of horse cases precede cases in human beings by 2 to 5 weeks.[60] Thus horses are sentinels for human beings in a given area. Clinical signs in human beings include fever, headache, confusion, stupor, and seizures, with a 5% to 15% mortality rate.[58]

Horses with VEE have sufficient circulating viral concentrations that they act as amplifiers of disease.[23,61] Ocular and nasal secretions from infected horses contain high concentrations of VEE.[16,17] Infection via entry through the respiratory tract may occur by direct contact with infected animals. Equine and human survivors of VEE infection and clinical disease may develop chronic relapsing viremias and serve as chronic disease amplifiers.[61] Clinical signs in human beings include fever, headache, myalgia, and pharyngitis. The mortality rate is 1%.[58]

With any of the alphaviral equine encephalitides, sufficient viral particles for infection may be present in central nervous and other tissues, and one should take precautions when performing a necropsy examination on suspect cases. Strict mosquito control and vaccination can prevent human and equine cases, and all equine cases should be reported to state health officials.[45,61]

10.13.1.2.9
Other Domestic Species

Calves may be affected naturally and experimentally with EEE.[62,63] Pigs may be affected by EEE[64] and VEE.[65] The signs of disease in these species are similar but are milder than disease in horses for the respective viruses. Burros and mules may contract all three diseases, and the disease is as severe as that identified in horses.[66]

10.13.1.3 PATHOGENESIS

After viruses are inoculated, they multiply in muscle, enter the lymphatic circulation, and localize in lymph nodes. Viruses replicate in macrophages and neutrophils and subsequently are shed in small numbers. Many of the viral particles are cleared at this time. If clearance mechanisms are successful, no further clinical signs develop. Neutralizing antibodies still will be produced. Several mechanisms of viral immunologic avoidance exist and include erythrocyte and leukocyte absorption. If viral elimination is not complete, the remaining viruses infect endothelial cells and concentrate in highly vascular organs such as the liver and spleen. Viral replication in these tissues subsequently is associated with circulating virus. The second viremic period often is associated with early clinical signs of disease. Infection of the central nervous system occurs within 3 to 5 days.[6,17,67,68]

10.13.1.4 CLINICAL SIGNS

Clinical signs are more profound in unvaccinated animals.[60,69] Acute clinical signs of EEE and WEE are nonspecific and include mild fever to severe pyrexia, anorexia, and stiffness. Viremia occurs during this period. After an experimental dose of EEE and WEE comes a 1- to 3-week incubation period. The incubation period is often shorter with EEE than WEE. Early signs of the diseases include fever and mild depression. This stage is transient and, presumably, often undetected because of lack of overt clinical signs. The acute signs may last for up to 5 days after they first manifest. Many cases of WEE do not progress beyond this point. 633
With EEE, progression is more common. Once nervous signs develop, the viremia is past, and animals are 634
unlikely to be able to amplify the disease. In progressive cases the fever may rise and fall sporadically. Cerebral signs may develop at any time but often occur a few days after infection. Acute signs often range from propulsive walking, depression, and somnolence to hyperesthesia, aggression, and excitability. Some horses may become frenzied after any sensory stimulation. Often conscious proprioceptive deficits are evident in the early stages. With progression, signs become less disparate and more consistent between EEE and WEE. The later signs are evidence of the dynamic nature of these conditions and increased severity of cerebral cortical and cranial nerve dysfunction. These signs include head pressing, propulsive walking, blindness, circling, head tilt, and facial and appendicular muscle fasciculations. Paralysis of the pharynx, larynx, and tongue is common. Death often is preceded by recumbency for 1 to 7 days. Comatose animals rarely survive. If animals are to survive, they show gradual improvement of function over weeks to months.[69–72]

VEE may have similar or different clinical presentations compared with WEE and EEE, which is most likely because of the difference in strain pathogenicity.[16,68] The pyrexia in cases of VEE peaks early and remains increased through the course of the disease. In experimental disease, endemic strains are associated with mild fever and leukopenia. Epidemic strains are associated with severe pyrexia and leukopenia.[6,68] Diarrhea, severe depression, recumbency, and death may be prominent before neurologic deficits are evident. Neurologic signs occur at approximately 4 days following infection. Other associated signs include abortion, oral ulceration, pulmonary hemorrhage, and epistaxis.[16,17]

10.13.1.5 DIAGNOSIS

The presumptive diagnosis is based on findings at clinical presentation and the presence of associated epidemiologic features. Serologic and necropsy evaluation provide a definitive determination.

10.13.1.5.1

Clinical Immunology and Virology

One usually identifies viral infections by complement fixation, hemagglutination inhibition, and cross-serum neutralization assays. A combination of these techniques increases the likelihood of a positive diagnosis.[73] A fourfold rise in antibody titer in convalescent sera commonly is recommended for diagnosis. However, one possibly may not detect a rise in titer. Viral antibodies are commonly present within 24 hours after the initial viremia, and their presence often precedes clinical encephalitis.[42] The concentration of antibodies increases rapidly and then decreases over 6 months.[74] An initial sample often is taken when encephalitic signs are present, which may be after titers have peaked. Therefore a second sample possibly may have a decreased titer compared with the initial sample. If increased titers exist for hemagglutination inhibition, complement fixation, and neutralizing antibody, then one can make a presumptive diagnosis on a single sample.[73] In the case of suspected VEE, an enzyme-linked immunosorbent assay can detect viral-specific immunoglobulin M antibodies to surface glycoprotein by 3 days after the onset of clinical signs. These antibodies are not produced in response to vaccine. The antibodies disappear by 21 days following infection.[74] One should use the assay for confirming acute VEE infection when one cannot collect convalescent serum samples. Viral cultures are unlikely to be fruitful, except in the case of acute VEE. One may isolate the virus from cerebrospinal fluid of horses with acute infections.[17] The usefulness of cerebrospinal fluid viral titers in light of a negative viral isolation is questionable. Fluorescent antibody, enzyme-linked immunosorbent assay, and viral isolation are useful in identifying virus in brain tissue.[75,76]

Colostral antibodies may interfere with diagnosis in foals. The antibody titers to VEE, WEE, and EEE viruses in the sera of 2- to 8-day-old foals are similar to those of dams. The serum half-life of maternal antibodies in foals is approximately 20 days.[77]

10.13.1.5.2

Clinical Pathology

The cerebrospinal fluid changes associated with togaviral infections are similar to those of other viral encephalitides and include increased cellularity (50 to 400 mononuclear cells per microliter) and protein concentration (100 to 200 mg/dl).

10.13.1.5.3

Necropsy Findings

For animals that die or are euthanized, one should perform necropsy and gross and histologic examinations with special reference to the central nervous system. The brain and spinal cord often have a normal gross appearance. In some cases vascular congestion and discoloration of the central nervous system is evident. Histologic findings include nonseptic mononuclear cell and neutrophilic inflammation of the entire brain.[16,78–80] Severe lesions are evident in the cerebral cortex, thalamus, and hypothalamus. Specific lesions include significant perivascular cuffing with mononuclear and neutrophil cell infiltration, gliosis, neuronal degeneration, and mononuclear cell meningeal inflammation. With VEE, liquefactive necrosis and hemorrhage of the cerebral cortex, atrophy of the pancreatic acinar cells, and hyperplasia of the pancreatic duct cells commonly occur.[79]

10.13.1.5.4

Differential Diagnosis

The differential diagnosis for EEE, WEE, and VEE should include other conditions associated with diffuse or multifocal neurologic deficits such as other togaviral encephalitides, trauma, hepatoencephalopathy, rabies, leukoencephalomalacia, bacterial meningoencephalitis, equine protozoal myeloencephalitis, and verminous encephalitis. 634 635

10.13.1.6

TREATMENT

No known effective, specific treatment of the viral encephalitides exists. Treatment is primarily supportive. Nonsteroidal antiinflammatory drugs (phenylbutazone, 4 mg/kg every 12 hours; flunixin meglumine, 1 mg/kg every 12 to 24 hours) control pyrexia, inflammation, and discomfort. Dimethyl sulfoxide given at 1 g/kg intravenously in a 20% solution may be useful in controlling inflammation and provides some analgesia and mild sedation. The use of corticosteroids is controversial because beneficial effects are short term and the risk of developing secondary bacterial infections increases. One may control convulsions with pentobarbital, 0.05 to 2.2 mg/kg diazepam administered intravenously, 2 mg/kg phenobarbital given orally, or 0.2 to 1.0 mg/kg phenytoin administered intravenously. If horses develop secondary bacterial infections, one should use appropriate antibiotic therapy. One should monitor hydration and administer balanced fluid solutions orally or intravenously as needed. Other supportive care should include dietary supplementation and administration of laxatives to minimize the risk of gastrointestinal impaction. If anorexia persists for more than 48 hours, one should use enteral or parenteral supplementation; one can use commercial formulations. For the short term, one may put pelleted feeds into suspension for oral administration. Protection from self-induced trauma may require protective leg wraps and head protection. If the horse is recumbent, one should attempt to provide support in a sling, and all animals should be bedded heavily.

10.13.1.7

PROGNOSIS

Complete recoveries from the neurologic deficits associated with these viruses are reported, but they are rare.[81] Animals that have recovered from EEE often have residual neurologic deficits that commonly include ataxia, depression, and abnormal behavior. Neurologic sequelae are similar but less common in horses that recover from WEE. For horses that develop neurologic disease, the mortality rate for EEE is 75% to 100%; for WEE, 20% to 50%; and for VEE, 40% to 80%.[16,42] If horses recover from any of the diseases, they seem to be protected variably for up to 2 years after infection. One would wisely assume that infection affords no protection.

10.13.1.8

PREVENTION

Prevention of these diseases should aim at reducing the concentration of insect vectors and implementing vaccination programs.[33–35,82–84] Most vaccines are killed (formalin-inactivated) viruses of chick tissue culture origin. Significant increases in antibody titer occur at 3 days after vaccination.[16,17,85–88] One should vaccinate susceptible horse populations with monovalent, divalent, or trivalent vaccines containing EEE, WEE, or VEE. Administration of trivalent vaccines increases specific antibody production to all viruses. Some cross-protection exists between EEE and WEE and between EEE and VEE, but none between WEE and VEE.[77,89,90] If one is to give VEE vaccine, simultaneous administration of all three vaccines is recommended.[91,92] The response to VEE vaccination alone is poorer in horses previously vaccinated against WEE and EEE.

[87,88,92,93] VEE vaccination does not seem to interfere with responses to EEE or WEE vaccination.[94] One should complete annual vaccinations in late spring or several months before the beginning of the encephalitis season. Adequate titers appear to last for 6 to 8 months. In areas in which the mosquito problem is prolonged or continuous, biannual or triannual vaccination is suggested. Vaccination of susceptible horses in the face of an outbreak is recommended. If vaccinated horses develop disease, the affected individuals are often young or old. Vaccination of mares 1 month before foaling enhances colostral antibody concentrations. Antibody concentrations in foals born to immunized mares appear by 3 hours after colostrum is fed and persist for 6 to 7 months.[77] Vaccination may begin at any age, but if they are vaccinated early, one should revaccinate foals at 6 months and 1 year to ensure adequate protection. Foals respond to vaccination with VEE in utero.[95]

Owners should use insecticides and repellents when possible and practical, should eliminate standing water, and in endemic areas or during an outbreak, should implement environmental insecticide application and should screen stalls. Horses with VEE can be persistently viremic and should be quarantined for 3 weeks after complete recovery. Cases of VEE must be reported in the United States. Other measures of disease control may be instituted by public health officials.

10.13.2 Flavivirus Encephalitis

Flavivirus species are associated sporadically with encephalitis in the United States and abroad. Seroconversion is often evident, but clinical disease is rare.

10.13.2.1 JAPANESE B ENCEPHALITIS

Sporadic cases of equine encephalitis have been observed, and serum neutralization tests have indicated the presence of Japanese encephalitis in affected horses.[96–102] In most instances, Japanese B encephalitis is a disease of human beings, and human beings are the source of infection for animals. 635

636

The disease is distributed widely throughout the eastern Pacific Rim. As in the case of most togaviral encephalitides, mosquitoes are the natural vectors. The mosquitoes *Culex tritaeniorhyncus* and *Culex pipiens* are the principal vectors. The virus may overwinter in these mosquitoes.[103] In general, horses are dead-end hosts, but horse- to-horse transmission by mosquitoes is reported.[104] A cycle that involves human beings, mosquitoes, and pigs maintains the infection throughout the year. Wading birds such as egrets are the major sylvatic hosts.[105] In pigs, which are a major reservoir, the disease is associated with abortion and nonsuppurative encephalitis in animals less than 6 months of age.[106] Subclinical infection occurs in cattle, sheep, and goats.[107]

Clinical signs of the disease in horses vary widely in presentation and severity. Mild signs are pyrexia, depression, and icterus for a few days. More severe signs include severe pyrexia and depression, icterus, and petechiation of mucosal surfaces. Dysphagia and ataxia are common. Transient signs may include radial paralysis, blindness, hyperexcitability, profuse sweating, and muscle tremor. These severe signs are uncommon but when present often precede death. In most cases, complete recovery occurs in 5 to 10 days. The disease is differentiated from other virus-associated encephalitides of horses by serologic and virus isolation tests.[104]

Formalin-attenuated vaccines protect against natural and experimental encephalitis in pigs and horses.[108]

10.13.2.2 BORNA DISEASE

Borna disease, first identified in Germany, and Near Eastern equine encephalomyelitis, found in the Middle East, are indistinguishable structurally and antigenically. The virus has a strict tropism for neural tissues, where it can persist indefinitely. The method of viral transmission is unknown but is thought to be by inhalation,[109] ingestion, or tick (*Hyalomma anatolicum*) transmission.[110] Other vectors may exist. The infection of horses is often accidental and outside an apparent tick and wild bird cycle. Morbidity is low, but mortality is high. Borna disease in Germany may be associated with transfer of virus from the Near East to Europe by migratory birds.

The signs of disease are similar to other equine encephalitides. The incubation period is unusually long and can range from 4 weeks to 6 months. The long incubation is due to the time required for transport of the virus in dendrite and axonal processes from the site of inoculation to the hippocampus. Necropsy findings are similar to other viral encephalitides, but intranuclear inclusion bodies in nerve cells of the hippocampus and olfactory lobes of the cerebral cortex are characteristic.[109,111]

The disease has zoonotic potential.[110,112,113] A vaccine is available that appears to be protective for horses.[110,114]

10.13.2.3 OTHER TOGAVIRIDAE

The following viruses have been classified as *Flavivirus* species. Some have been classified into other groups of viruses from time to time.

California encephalitis is caused by a group of closely related viruses. California serogroup viruses often are classified as Bunyaviridae, as well. The important vectors seem to be *Aedes dorsalis, A. triseriatus,* and *Culex tarsalis,* and they can be associated with encephalitis in horses (snowshoe hare virus).[115] Seroconversion without clinical disease is widespread.[43,60,87,116–121] In the rare instance when horses develop clinical disease, they often recover completely within 7 to 10 days. Pyrexia and depression appear to be common signs.[116,120–122]

St. Louis virus is associated most commonly with encephalitis in human beings and may be involved in equine disease. Experimental inoculation in horses produces viremia but no clinical signs. Neutralizing antibody is often present. *Culex pipiens* and *C. tarsalis* are the major vectors. Wild birds seem to be the primary reservoir.[26,123–125]

West Nile virus meningoencephalitis occurs in horses in the French Mediterranean. Seroconversion without evidence of disease occurs in human beings, sheep, pigs, and birds. *C. molestus* appears to be the important vector.[126–128]

Powassan virus has been associated with nonsuppurative, focal necrotizing meningoencephalitis in horses. Antibodies for Powassan virus commonly are identified in Ontario and the eastern United States. *Ixodes cookei, I. marxi,* and *Dermacentor andersoni* appear to be important vectors, with snowshoe hares and striped skunks as major reservoirs. Zoonoses occur after bites by infected ticks. Approximately 13% of horses sampled across Ontario in 1983 were serologically positive for the virus.[129] Experimental infection with Powassan virus strain M794 in horses was associated with neurologic deficits within 8 days. A nonsuppurative

encephalomyelitis, neuronal necrosis, and focal parenchymal necrosis occur. Signs include tremors of the head and neck, ptyalism, myalgia, ataxia, and recumbency. No clinical signs were identified in inoculated rabbits, but widespread encephalitis characterized by lymphoid perivascular cuffing, lymphocytic meningitis, and lymphocytic choroiditis occurred.[43,129]

Main Drain virus was isolated from the brain of a horse with encephalitis in Sacramento County, California. Signs included incoordination, ataxia, stiffness of the neck, head pressing, dysphagia, pyrexia, and tachycardia. The major vector is *Culicoides varipennis,* which transmits the virus from infected rabbits and rodents.[122]

Horses have been identified with titers for Ross River and Murray Valley viruses. Experimental infection with either virus produced transient pyrexia, myalgia, and ataxia. Horses are unlikely to be efficient amplifiers of either virus or important pathogens.[130–133] In Australia, significant titers for Murray Valley encephalitis virus have been identified. The virus is more commonly a disease of human beings. An epidemic in human beings was associated with significant titers in horses. Some horses with clinical signs, significant titers, and histologic evidence of viral encephalitis were identified.[130,133] 636 637

In Michigan, evidence of Cache Valley and Jamestown Canyon virus were identified in clinically normal horses.[125] Other viruses, identified in areas around the world, that have been implicated in equine encephalitis or that are associated with encephalitis in other species and for which significant titers have been identified in horses include the louping ill,[134,135] Maguari,[26,117,136] Ross River,[133] Aura,[26,136] Una,[26,136,137] Highlands J,[48,125,138] Semliki forest,[139] and Getah viruses.[102]

10.14

10.14—West Nile Virus Encephalitis

William J. Saville

West Nile virus had never been seen in the Western Hemisphere before 1999. The virus has a geographic range greater than any other known arbovirus and is found throughout Africa, northern to central Europe, and eastern Asia. The virus was isolated first from the blood of a woman in Uganda in 1937. The earliest reported epidemic of West Nile encephalitis occurred in Israel in 1957 but was recognized retrospectively. That outbreak involved more than 500 hospitalized patients.[1] The largest epidemic of West Nile encephalitis on record occurred in South Africa during 1974. This epidemic involved an area of about 2500 km^2 in the Karoo and southern Cape provinces and resulted in thousands of human infections. More recently, epidemics of West Nile encephalitis have occurred in Romania (1996 to 1997), Czechland (1997), Italy (1998), and Russia (1999) so that the virus is considered a reemerging mosquito-borne disease in Europe.[2] How or when West Nile virus was introduced into the United States is unknown. Speculation places the introduction through the importation of birds or possibly a mosquito transported into the United States by ship or airplane.

West Nile virus is a member of the Japanese encephalitis virus complex of the genus *Flavivirus,* family Flaviviridae. This genus of viruses is found in several countries around the world, and some of the common members of this serocomplex include the viruses for Japanese encephalitis, Murray Valley encephalitis, St. Louis encephalitis, and West Nile encephalitis and Kunjin virus.[2] Up until 1999 the only members of the *Flavivirus* detected in North America were those causing Powassan and St. Louis encephalitides. The epidemiology of West Nile virus is nearly identical to that of St. Louis encephalitis. In both diseases the agents are transmitted principally

by species of *Culex* mosquitoes and have birds as the reservoir. The diseases do differ in that West Nile virus causes disease and mortality in wildlife (birds, particularly crows and blue jays) and domestic animals (particularly horses).[1] Although St. Louis encephalitis virus does not cause any remarkable disease in wildlife or domestic animals, it and West Nile virus can cause disease in human beings.

10.14.1 Epidemiology

Early outbreaks of West Nile virus encephalitis in horses occurred in 1962 in France, 1963 in Egypt, 1996 in Morocco, 1998 in Italy, and now 1999 to 2002 in the United States.[2,3] Other outbreaks of West Nile virus occurred in the Camargue region of France and in Israel in 2000.[4,5] In the outbreak in France in the early 1960s, researchers recorded a 10% morbidity and 30% mortality rates.[6] In 1959 in Egypt, researchers reported seroprevalence of antibodies to West Nile virus of 14% to 89%, depending on the area tested. However, morbidity and mortality data were not available.[7] In Morocco the case fatality rate was 44.7% (42 of 94), and in Italy was 6 of 14 (43%).[2,8] In the outbreak in France in 2000, the fatality rate was 34 % with an overall seroprevalence of infection of 8.5%.[4] In contrast, the case fatality rate in Israel was much lower (19.7%).[5] In the United States in 1999, 9 of 25 (36%) horses with clinical signs of the disease died or were euthanized. Sixty cases of West Nile virus were reported in horses in 2000 from seven states with a case fatality rate of 38% (23 of 60). Almost 80% of the cases were from New York and New Jersey (46 of 60, or 77%), with 7 cases from Connecticut, 4 from Delaware, and 1 each from Massachusetts, Pennsylvania, and Rhode Island. The cases of equine West Nile virus in 2000 started in mid-August and ended in October. The age range of the horses was from 4 months to 38 years with a mean age of 14 years. More males were affected (36 of 60) than females, and a breed predilection was not apparent because 11 breeds were affected.[3] In 2001, 738 equine cases of West Nile virus were confirmed in the United States in 19 states, with an estimated case fatality rate of 25%. The first equine case in 2001 occurred in June, which is different from the previous 2 years in the United States. Rapid spread of the virus in 2002 in the United States resulted in 14,717 confirmed cases of West Nile virus and likely many unconfirmed cases. The number of cases in horses is spread over 40 states and several provinces in Canada, and the U.S. Department of Agriculture has estimated a 28% case fatality rate for 2002.

640

641

10.14.2 Pathogenesis

Following the bite of a West Nile virus–infected mosquito, one can detect the resulting viremia in some horses but not in others. A study of experimental infections performed in the early 1960s demonstrated viremias in two of six donkeys and none of three horses inoculated. The viremia in the two donkeys lasted for 1 day.[7] In a recent study performed in the United States, infection with West Nile virus via *Aedes albopictus* mosquitoes resulted in viremias in seven of eight horses.[9] None of the viremias lasted more than 6 days, and the highest viremia in one horse was 460 Vero cell plaque forming units (PFUs) per milliliter.[9,10] After infection of the eight horses in the U.S. study, naïve mosquitoes were allowed to feed on all viremic horses. None of the mosquitoes allowed to feed on infected horses became infected.[10] The viremias in horses appear to be of low magnitude and short duration; therefore horses are unlikely to serve as important amplifying hosts in nature.[7,10] Neutralizing antibody titers developed within 7 to 11 days after infection in an experimental trial.[10] Recent studies in human beings infected with the West Nile virus have demonstrated neutralizing antibody titers for greater than 2 years. Some horses infected during the 1999 outbreak that have been tested subsequently for neutralizing antibody still have titers after 15 months,[3] which suggests that protection from a natural infection may be long term.

10.14.3 Clinical Signs

Not all horses infected with the West Nile Virus develop clinical signs of the disease whether naturally or experimentally infected.[3,5,7–9] The incubation period for development of clinical signs is difficult to establish; however, experimental infection resulted in development of clinical signs of encephalitis 8 days after inoculation in one horse.[9] All horses examined in an outbreak of the disease in Italy exhibited varying degrees of ataxia and weakness in the pelvic limbs. Asymmetric weakness was detectable in the rear limbs of some horses and involved one or both thoracic limbs in some horses. In six horses, clinical signs progressed with ascending paresis leading to tetraplegia and recumbency within 9 days. Depressed mental state and tremors were notable in a few cases; however, no behavioral or head posture abnormalities or signs of cranial nerve involvement were apparent.[8] In the United States, most of the horses with encephalitis were ataxic (85%), almost half were weak (48%), many were recumbent or had difficulty rising or both (45%), muscle fasciculations were common (40%), less than one fourth of the horses had fevers (23%), and less than one fifth had paralyzed or droopy lip (18%), a twitching face or muzzle (13%), teeth grinding (7%), and blindness (5%).[3] Interestingly, the equine cases in Israel were similar to those in the United States. Behavioral and cranial nerve abnormalities occurred in some horses in Israel that may be related to the strain of virus (Is98), which is similar to the strain found in the United States (NY99).[5]

10.14.4 Differential Diagnosis

One would have to consider rabies, botulism, equine protozoal myeloencephalitis, cervical vertebral myelopathy, equine herpes virus meylopathy, equine degenerative myelopathy, and other encephalitides such as western equine encephalitis, eastern equine encephalitis, and Venezuelan equine encephalitis in the differential diagnosis.
Behavioral abnormalities and ascending paralysis make rabies a primary differential diagnosis. In addition, many 641
cases of West Nile virus exhibit mild to severe muscle fasciculations, making botulism another primary 642
differential diagnosis. Many cases also are similar to commonly diagnosed neurologic diseases, particularly equine protozoal myeloencephalitis. Therefore diagnostic rule-outs are necessary.

10.14.5 Pathologic Findings

No gross pathologic lesions were detected in the Italian cases but did occur in some cases in the United States. Histologically, all animals exhibited slight to moderate nonsuppurative encephalomyelitis, primarily in the spinal cord and lower brainstem affecting gray and white matter. In some cases, moderate to severe hemorrhage was notable in the spinal cord. The most severe lesions were in the thoracic and lumbar spinal cord.[11] The lesions in the United States cases in which postmortems were performed were similar to those found in the Italian cases, except the brainstem lesions were more severe in the United States cases.[12] Unlike encephalitis caused by alphaviruses such as western equine encephalitis and eastern equine encephalitis, significant changes to the cerebral and cerebellar cortices were not apparent.[13]

10.14.6 Diagnosis

Routine complete blood counts and serum biochemical assays resulted in finding all values within their normal ranges in the few horses tested. Similarly, cytologic examination of the cerebral spinal fluid (CSF) was normal in all but one horse with a low white blood cell count. The total protein was normal in CSF of all horses except one

that had a high total protein with xanthochromia.[12] In a more recent study of 30 cases, cytologic findings of the CSF and protein concentration in only 8 of 30 horses were within normal ranges. Of the 22 horses with abnormal CSF results, 16 had a mononuclear pleocytosis with normal protein and the other 6 horses had normal cytologic findings with an increased protein concentration.[14]

Several serologic tests have been used to diagnose West Nile virus disease, including plaque reduction neutralization, hemagglutination inhibition, complement fixation, enzyme-linked immunosorbent assay (ELISA), and antigen capture ELISA. One also may attempt virus isolation from whole blood, serum, CSF, and brain or spinal cord tissues. Other diagnostics include reverse transcriptase polymerase chain reaction testing of central nervous system (CNS) tissues and immunohistochemistry.[1] In veterinary diagnostic laboratories, hemagglutination inhibition has been the most common test and has demonstrated greater sensitivity than complement fixation.[13] The plaque reduction neutralization test requires BSL3 laboratory capabilities; therefore, few laboratories are equipped to perform this test. In the United States, most of the samples have been tested by the National Veterinary Services Laboratory in Ames, Iowa. In the acute cases of West Nile virus encephalitis in horses, antigen capture ELISA has been used to detect West Nile virus–specific immunoglobulin M (IgM). In experimentally and naturally infected horses, IgM antibodies were detectable within 8 to 10 days and persisted for less than 2 months. Immunoglobulin M antibodies have not been detected in vaccinated horses; therefore, this test is useful even if the disease becomes endemic. In the study by Ostlund, Crom, Pederson, et al., the authors were able to isolate West Nile virus from the CNS tissues in some (7 of 10) horses and detect West Nile virus RNA using reverse transcriptase polymerase chain reaction testing in all 10 horses from which brain tissue was submitted.[3] Most state diagnostic laboratories have the capability of performing two ELISA tests for West Nile virus–specific IgM and IgG. Veterinarians should consult with their state departments of agriculture and departments of health to determine sampling required and where samples are to be sent.

10.14.7 Treatment

Supportive care is the only treatment available. Antiinflammatory medications such as nonsteroidal antiinflammatory drugs, steroids, and dimethyl sulfoxide (10%) may help to alleviate central nervous system inflammation and pain. One may treat CNS edema using mannitol (0.25 to 2 g/kg intravenously), and vitamin E (5000 to 8000 IU/day orally) may help to alleviate oxidant injury. Several other treatments have been attempted, such as ribavirin and interferon, as antiviral agents; however, the efficacy of these medications is unknown. Additionally, some clinicians are using hyperimmune plasma based on limited use in human beings. Whether these novel treatments are helpful remains to be determined. Some horses may require intravenous fluids and possible nutrient support. Some horses that are recumbent and unable to rise require support by slings as well.[13] For horses unable or reluctant to receive oral medications, one may insert a feeding tube (Mila International Inc., Florence, Kentucky).

10.14.8 Prevention

Two methods exist for preventing or controlling West Nile virus infections in horses and both are important: integrated mosquito control and vaccination. The integrated mosquito control includes reduction of mosquito breeding sites and the use of larvicides and adulticides. The more breeding sites are controlled, the less pesticide is required. Owners should house horses indoors during peak periods of mosquito activity (dusk and dawn), 642
643
should avoid turning on lights inside the stable during the evening and overnight, because mosquitoes are attracted to lights, and should place incandescent bulbs around the perimeter of the stable to attract mosquitoes away from the horses. Black lights do not attract mosquitoes well. Owners should remove all birds that are in or

close to the stable to reduce the potential reservoirs and should eliminate areas of standing water on their property. Shallow standing water, used tires, manure storage pits, and drainage areas with stagnant water are ideal mosquito breeding places. Topical preparations containing mosquito repellents are available for horses. One should read the product label before using and should follow all instructions. Fans blowing on the horses in the stable help deter mosquitoes. Owners should fog the stable premises with a pesticide in the evening to reduce the number of mosquitoes and should read directions carefully beforehand. Local mosquito control authorities may be able to help in assessing the mosquito breeding risks associated with a client's property.

The second method of controlling West Nile virus infections in horses is vaccination. A vaccine was developed using killed virus and has been sold under a conditional licence since August 2001. Some recent data from the company developing the vaccine suggest that the vaccine is efficacious. The study used 19 vaccinated horses and 11 controls. Horses were vaccinated 12 months before challenge. Although 9 of 11 controls developed viremia, only 1 of 19 of the vaccinated horses became viremic, suggesting that vaccination reduces viral replication. In addition, none of the study horses developed a fever.[15] More recent data, based on follow-up of West Nile virus cases from Ohio, suggest the vaccine is effective in reducing the risk of death from West Nile virus infection. The data indicate that 5.9% of horses died after receiving 2 or more vaccinations, which is similar to the percentage of horses in the experimental challenge that developed viremia (5.3%).

No efficacy data are available at this time regarding protection during natural infections; however, the efficacy is expected to be similar to that of the killed virus vaccine for Japanese encephalitis. Japanese encephalitis virus belongs in the same serocomplex as West Nile virus. The Japanese encephalitis vaccine was developed in Japan in the early to mid-1940s, and the Japanese Ministry of Agriculture studied the efficacy of the vaccine in 1948. The ministry found the clinical encephalitis cases among horses that had received two vaccinations before the epidemic season was 0.05% (51.6 per 100,000), whereas the clinical encephalitis cases among nonvaccinated horses was 0.44% (443.5 per 100,000).[16] Therefore the relative risk for Japanese encephalitis in nonvaccinated horses in Japan was greater than 8 times higher than in vaccinated horses. Further evidence that the vaccine has been effective in Japanese horses is the reduction in clinical encephalitis cases in horses in Hokkaido, Japan, from 337.1 per 100,000 horses in 1948 to none in 1967. Similar results were apparent after the initiation of vaccination in Singapore.[17] A vaccine also has been developed in China, and current efficacy data demonstrate that the risk of clinical Japanese encephalitis in unvaccinated horses (172.1 per 100,000) was 7.5 times higher than in horses that had been vaccinated (23 per 100,000).[18] A new vaccine is being developed in the United States to prevent West Nile virus encephalitis in horses. The new vaccine is a recombinant DNA vaccine that includes a Japanese encephalitis virus signal sequence in the plasmid. This DNA vaccine provided 100% protection in mice and horses from West Nile virus–infected mosquitoes.[9] Therefore because West Nile virus and Japanese encephalitis are in the same serocomplex, the successful reduction of clinical cases of Japanese encephalitis in several countries using the killed Japanese encephalitis vaccine, construction of the new West Nile virus DNA vaccine using Japanese encephalitis virus sequences, the efficacy data of the challenge trial and the Ohio data, the West Nile virus vaccine is expected to be reasonably efficacious. The author recommends administering the West Nile virus vaccine initially in two doses 3 to 6 weeks apart and then yearly afterward. The second dose should be given at least 4 weeks before the beginning of the mosquito season. If the horses are show horses or racehorses that are being transported frequently (highly stressed), the author suggests administering an additional booster in the last week of July or the first week in August.

10.15

10.15—Rabies

Carla S. Sommardahl

643

10.15.1 Epidemiology and Pathogenesis 644

Rabies is an uncommon disease in the equine, but because of its zoonotic potential, one should consider it in the differential diagnosis in horses showing neurologic signs of less than 10 days' duration. In the United States during 1993, 606 cases of rabies were reported in domestic animals, with 0.5% of these being in horses and mules.[1]

The rabies virus is a large, cylindric, bullet-shaped neurotropic rhabdovirus (genus *Lyssavirus,* family Rhabdoviridae).[2] Rhabdoviruses are enveloped with single-stranded RNA. They are heat-labile and are susceptible to degradation by radiation, strong acids, alkalis, most disinfectants, lipid solvents, and anionic solvents.[2,3] Rabies virus is transmitted by saliva-contaminated wounds. In the horse the most common method of infection is a bite wound from a wild carnivore or insectivorous bat carrying the virus.[4] The most common reservoir hosts in the United States are skunks, raccoons, and the red fox.[2] However, domestic dogs, cats, and other horses may transmit rabies to horses by bite wounds. Furthermore, rabies virus can be transmitted by droplet inhalation, orally, or transplacentally. Droplet transmission has been reported to have occurred in foxes, coyotes, opossums, and raccoons in a bat cave in Texas. In that report the virus was isolated from the air in the cave.[5] Aerosolization of the virus also caused an outbreak of rabies in a laboratory. Transplacental transmission of the virus has occurred in naturally infected cattle and experimentally infected mice and bats.[2]

Rabies virus infects and replicates in myocytes at the inoculation site and may remain undetectable for weeks or months before moving centrally. The virus infects peripheral nerves by traversing neuromuscular and neurotendinous spindles. Progression along the nerve is thought to occur in the tissue spaces of the nerve fasciculus.[5] After progressing centripetally up the peripheral nerve by axoplasmic flow, the virus replicates in spinal and dorsal root ganglia of the corresponding peripheral nerve. Once the virus reaches the central nervous system (CNS), spread occurs rapidly through multiplication in neurons of the brain, spinal cord, sympathetic trunk, and glial cells. Spread of rabies virus also can occur through passive transport within cerebrospinal fluid or blood.[2–4] Finally, the virus reaches tissues outside the CNS via centrifugal movement of the virus along nerve axons.[2,3]

The incubation period for rabies varies from 9 days to 1 year in horses. The incubation period can be affected by the virus strain, host species, inoculum size, and proximity of the inoculation site to the CNS.[2,4] Retention of virus in myocytes at the inoculation site may be a mechanism for variation in the incubation period. A shorter incubation period also may be explained by the virus entering peripheral nerves soon after exposure and rapidly migrating centripetally to the CNS without replication in nonneural tissue.[2]

10.15.2 Clinical Signs

No signs are pathognomonic for rabies infection in horses. Clinical signs on presentation vary and range from lameness to sudden death.[6–9] Hyperesthesia, ataxia, behavior change, anorexia, paralysis or paresis, and colic have been reported as initial clinical signs.[6–11] One rarely finds a bite wound, and the horse may or may not be febrile. The site of inoculation and its proximity to the CNS influence what clinical signs one observes.[2,7,8] The 644
neurologic signs exhibited in rabies-infected horses can be classified into three forms depending on the 645
neuroanatomic location in the CNS infected by the virus. First, in the cerebral or furious form, one may see aggressive behavior, photophobia, hydrophobia, hyperesthesia, straining, muscular tremors, and convulsions.[12]

Second, in the brainstem or dumb form, one commonly sees depression, anorexia, head tilt, circling, ataxia, dementia, excess salivation, facial and pharyngeal paralysis, blindness, flaccid tail and anus, urinary incontinence, and self-mutilation.[10,12,13] Finally, in the paralytic or spinal form, one sees progressing ascending paralysis, ataxia, or shifting lameness with hyperesthesia, and self-mutilation of an extremity.[11–14] Most affected animals with the paralytic form become recumbent in 3 to 5 days, with normal eating and drinking often remaining.[13] The neurologic signs may vary as the virus spreads to other portions of the CNS. Thus horses may have clinical signs of two or all forms of rabies. Disease progresses rapidly, and death is usually inevitable regardless of the clinical manifestation. Antiinflammatory therapy can delay virus progression,[12] but death usually occurs within 5 to 10 days after onset of clinical signs.[9,13]

10.15.3 Diagnosis

Antemortem diagnosis of rabies is difficult, but one should consider the disease in horses showing rapidly progressing or diffuse neurologic signs. Other diseases that one should consider include hepatoencephalopathy, togaviral encephalitis, protozoal encephalomyelitis, nigropallidal encephalomalacia, botulism, lead poisoning, cauda equina neuritis, meningitis, space-occupying mass, trauma to the brain or spinal cord, and esophageal obstruction.[3,5,13] Clinical laboratory data of body fluids are nonspecific. Cerebrospinal fluid may be within normal reference range or may show a moderate increase in total protein concentration (60 to 200 mg/dl) and a pleocytosis (5 to 200/dl).[3,5,13] Fluorescent antibody testing of tactile hair follicles of facial skin taken on biopsy or corneal epithelium may help diagnose rabies ante mortem. The fluorescent antibody technique detects the rabies virus antigen in these tissues. Unfortunately, a negative test does not exclude rabies as a differential diagnosis.[9] One can achieve definitive postmortem diagnosis by submitting half the brain in 10% formaldehyde for histologic examination and the other half frozen to a public health diagnostic laboratory for immunofluorescent antibody tests, mouse inoculation, and monoclonal antibody techniques. The whole brain may be shipped unfrozen on ice for further rabies evaluation and testing. One should examine the rest of the carcass only with careful precautions against transmission of the virus, if present, by wearing gloves, caps, and masks until a negative rabies diagnosis is made.

Common histopathologic changes are a mild, nonsuppurative encephalomyelitis, perivascular cuffing by mononuclear cells, gliosis, glial nodules, and neuronal degeneration.[3,13] These lesions occur most commonly in the hippocampus, brainstem, cerebellum, and gray matter of the spinal cord. Large intracytoplasmic eosinophilic inclusions within neurons and ganglion cells, known as Negri bodies, are pathognomonic for rabies.[2,3,13] However, in 15% to 30% of confirmed rabies cases, Negri bodies are not present in histopathologic sections, especially if the animal died or was euthanized early in the disease process.[2] The most commonly used and fastest diagnostic test for rabies is the fluorescent antibody test. This technique may identify 98% of infected brain specimens. The mouse inoculation test is the most accurate method for diagnosing rabies virus infection but requires 5 to 6 days to complete. The mouse inoculation test involves the injection of suspect brain or salivary gland tissue homogenates intracerebrally in mice and observation of clinical and neurologic signs or death.[2,3] The monoclonal antibody test has been used most recently for rabies diagnosis in horses. The test can differentiate specific street, fixed, or vaccinal strains of rabies virus by their glycoprotein or nucleocapsid antigens.[2] This is important in postexposure vaccination of human beings and animals when using the specific strain of virus.

10.15.4 Treatment and Prevention

No specific treatment exists for rabies in horses. Symptomatic treatment and supportive care may help prolong the disease course to complete diagnostics and to rule out other diseases with similar signs. Prolonging the course, however, creates a risk of exposure to handlers and other animals. Therefore one should isolate any animal suspected of having rabies and should handle it as little as possible. Horses that are known to have been exposed to rabies should have all wounds cleaned and lavaged with iodine or quaternary ammonium disinfectant, and rabies antiserum, if available, infiltrated around the bite wound.[3,13] No postexposure protocol exists for unvaccinated or vaccinated horses. However, exposed horses should be quarantined for 6 months and observed for the occurrence of neurologic signs. Unvaccinated horses should not receive postexposure prophylaxis until after the 6 months of quarantine. Two inactivated diploid vaccines (Imrab-1, Pitman-Moore, Inc., Terre Haute, Indiana; and Rabguard, Norden Laboratories Inc., Lincoln, Nebraska) are approved for use in horses. These vaccines are recommended to be given annually in high-risk areas to horses older than 3 months of age.[12,13] The dosage is 2 ml administered in the semimembranosus or semitendinosus muscle group. The manufacturer does not recommend administration into the neck muscles.[4] 645

646

Several arguments are ongoing concerning vaccination of horses against rabies. The potential for a rare vaccine reaction—illness with neurologic signs following the use of a modified live virus (SAD strain) rabies vaccine—has been reported in the United States.[6] The risk also exists that vaccinated horses bitten by a rabid animal will confer a silent or attenuated form of the disease, and the animal will shed the virus.[12] This theory, however, is not proven. Public concern and safety outweigh the potential risks of vaccinating horses. Therefore one should follow recommendations to vaccinate in endemic areas. One should report any animal positively diagnosed with rabies to public health officials.

10.16

10.16—Equine Motor Neuron Disease

Yvette S. Nout

Equine motor neuron disease (EMND) is an acquired neurodegenerative disease of adult horses that has been reported in North and South America, Japan, and Europe.[1–9] Lower motor neuron disease was recognized in 1988 based on histologic changes in skeletal muscle,[10] and EMND was first described in 1990.[1] In the 1990s, EMND was recognized worldwide in an apparently increasing frequency[3,11]; however, recently the number of EMND cases appears to be decreasing.[9] The decrease may be caused by preventive management measures taken for horses at risk of developing the disease.

The disease affects primarily the motor neurons in the spinal cord ventral horn cells and brainstem and leads to characteristic clinical signs including generalized neuromuscular weakness and neurogenic muscle atrophy.[1,2,5,12] Equine motor neuron disease closely resembles human motor neuron disease, which is known as amyotrophic lateral sclerosis (ALS) or Lou Gehrig disease.[1,13] However, EMND only affects the lower motor neurons, which is not the case in ALS. A chronic lack of antioxidants is implicated in the pathogenesis of this disease.

10.16.1

Clinical Signs

EMND occurs in adult horses with a mean age of onset of clinical signs of 9 years (range of 2 to 23 years).[14] The risk for EMND increases with age, peaking at around 15 years.[15] Quarter Horses appear at increased risk for developing EMND; however, this may reflect management factors.[2,15] No gender predilection is apparent.

Clinical signs vary depending on the stage or duration of the disease. Currently, a subacute and a chronic form are recognized.[9]

10.16.1.1

SUBACUTE FORM

During the early phase of EMND, trembling, muscle fasciculations, base-narrow stance, shifting of weight in the rear limbs, abnormal sweating, excessive recumbency, muscle atrophy, and weight loss despite a normal or even ravenous appetite are the most characteristic clinical signs (Figure 10.16-1).[1,2,6,8,9] Ataxia is not a clinical sign of EMND. A horse with EMND moves better than it stands.[2,8] Muscle wasting is most noticeable in the quadriceps, triceps, and gluteal areas. In more than 50% of cases horses may display a lower than normal head carriage with muscle wasting of the cervical musculature (hangdog appearance).[8] Onset of 646
muscle wasting may occur for approximately 1 month before the acute onset of clinical signs. 647

Figure 10.16-1 Characteristic appearance of a horse with equine motor neuron disease, including muscle wasting, sweating, base-narrow stance, low head carriage (hangdog appearance), and tail head elevation.

10.16.1.2 CHRONIC FORM

Owners may present horses for poor performance, gait abnormalities (stringhalt-like movement), and failure to gain weight. Trembling and muscle fasciculations are not pronounced in the chronic form of EMND. Horses with the chronic form of EMND are often horses that have stabilized from the subacute form; however, some horses develop the chronic form without experiencing the subacute form. Muscle atrophy varies from mild to severe, and some horses may appear emaciated.[1,8,9]

10.16.1.3 SUBCLINICAL FORM

Experimental evidence indicates that horses may develop a subclinical form of EMND, which may affect performance and safety.[8,9]

In the subacute and chronic forms of EMND the tail head often is elevated because of denervation atrophy and fibrotic contracture of the sacrococcygeus dorsalis medialis muscle.[6,8,9] In approximately 30% of cases, ophthalmoscopic examination may reveal a distinctive retinopathy with a mosaic pattern of brown pigment deposition in the fundus. These horses are not necessarily visually impaired.[16,17]

10.16.2 Pathologic Findings

Gross necropsy findings in EMND include diffuse muscle atrophy and pallor of especially the intermediate vastus and medial head of the triceps muscles. The central nervous system and peripheral nerves are grossly normal. Histologically, one may detect noninflammatory neuronal degeneration and neuronal loss at all levels of the spinal cord, but such loss is most obvious in the cervical and lumbar intumescence. One finds the lesions in the ventral horn cells (lower motor neurons) of the spinal cord gray matter; the nuclei of cranial nerves V, VII, and XII in the brainstem; and the nucleus ambiguus. Secondary axonal degeneration with loss of myelinated fibers because of dysfunction or death of these motor neurons is present in the ventral spinal roots; spinal nerves; cranial nerves V, VII, IX (sometimes), and XII; and peripheral motor nerves.[1,12] Peripheral motor nerve degeneration also may be evident on antemortem muscle biopsy.[18]

Skeletal muscle changes include nonspecific myopathic changes such as excessive fiber size variation, internal nuclei, and cytoarchitectural alterations. Scattered fiber degeneration and necrosis is a consistent finding in EMND. Atrophy of type I and type II muscle fibers occurs in severely affected muscles in EMND and is pathognomonic of denervation atrophy.[1,12,13] EMND predominantly affects type I fibers, in contrast to denervating diseases in other species, and has not been reported in ALS. Motor neurons supplying the type I fibers have a higher oxidative activity and thus may be more susceptible to oxidative injury.[12] Similar to ALS, where at least 30% of motor axons must be destroyed before clinical evidence of atrophy occurs, in horses with muscle wasting caused by EMND, a mean motor neuron loss of 31% was recorded.[19]

A pigment retinopathy may be visible, as well as deposition of lipopigment in the endothelial capillaries of the spinal cord. These findings have been reported in other animals with vitamin E deficiency.[16,17] Besides the abnormalities in the neuromuscular system, no other pathologic findings have been found consistently in horses with EMND.

10.16.3 Pathophysiology

The clinical signs of neuromuscular weakness result from the generalized denervation muscle atrophy found in horses with EMND. The pathogenesis of the neuron damage and death in EMND is not understood fully but is thought to result from free radical damage. Equine motor neuron disease occurs sporadically and affects horses of all ages and breeds. Therefore infectious agents or environmental toxins are less likely to be a cause of the disease.[2]

A chronic vitamin E deficiency is thought to be the most important factor in the cause of EMND based on the fact that affected horses consistently have low plasma vitamin E concentrations and have not had access to pasture or green forages for a prolonged time.[2,11,15,20] Vitamin E concentrations in the central nervous system, 647

648 peripheral nerves, muscle, liver, and adipose tissue have been found to be correlated to blood concentrations.[9] Horses generally have been on the same premises for more than 2 years before developing clinical signs.[15] The type I muscle fiber atrophy and the lipopigment deposition in the capillaries of the spinal cord are pathologic findings suggesting an oxidative type of injury as a cause of the neuronal death.[13] The pigment retinopathy found in approximately 30% of cases and the lipopigment deposition in the vasculature of the spinal cord occurs in other species and is related to a vitamin E deficiency.[8,16]

Equine degenerative myeloencephalopathy, another neurodegenerative disease in horses, also is associated with a vitamin E deficiency; however the central nervous system lesions in equine degenerative myeloencephalopathy are different from those in EMND. Vitamin E deficient adult horses have been suggested to develop EMND after a transitory period of triggering events such as exposure to neurotoxins or excessive amounts of prooxidants.[2,9] So far a neurotoxin has not been identified. The presence of prooxidants such as copper and iron in spinal cord, liver, and plasma has been investigated but has not been confirmed to play a role in the development of EMND.[9,21]

Although EMND is the only naturally occurring model for ALS[13] and oxidative injury is implicated in the cause of both diseases, some important differences exist between the two.[6,12,13] In contrast to EMND in which the disease process is limited to the lower motor neurons, ALS affects upper and lower motor neurons. Only mild degeneration of the pyramidal tracts is present in horses with EMND, but the pyramidal tracts in horses are less extensive and poorly developed compared with human beings. ALS is familial in approximately 10% of cases, and 20% of patients with familial ALS carry a mutation of the Cu/Zn superoxide dismutase 1 gene.[22] This metalloenzyme is one of the principal oxygen-derived free radical scavengers and protectants against oxidant injury to the nervous system. The mutation of this gene leads to an altered form of the enzyme that is actively toxic to cells.[23] In these patients the quantity of oxidants is increased, whereas in horses with EMND a lack of antioxidants is the presumed cause of neuronal degeneration and death.[2,24] Mutations in the Cu/Zn superoxide dismutase 1 gene have not been found in EMND.[25] The cause of spontaneously occurring ALS is unknown; however, the similarities between familial ALS and spontaneous ALS suggest a common pathway for neuronal death.[13] The question of why the disease affects motor neurons so selectively has not been answered thus far. Motor neurons are particularly susceptible to oxidative injury by having high energy requirements associated with the maintenance of long axons. The high concentration of polyunsaturated fatty acids in neuronal cell membranes make these cells particularly susceptible to lipid peroxidation.[26] A recent investigation has shown that chronic or episodic deficits in oxygen and glucose, through an altered function of vascular endothelial cell growth factor, result in a failure of the motor neurons to meet their metabolic requirements. This altered function of vascular endothelial cell growth factor resulted in ALS-like symptoms and neuropathy.[27] If a relationship between superoxide dismutase 1 and altered vascular endothelial cell growth factor function exists, it remains to be investigated.

10.16.4 Diagnosis

Clinical signs and a history of other EMND cases in the stable and absence of pasture or green hay may lead to a tentative diagnosis of EMND. Ophthalmoscopic examination may reveal fundic lesions in approximately 30% of cases. Serum enzyme activities of aspartate aminotransferase and creatine kinase are generally mildly to moderately increased. The plasma vitamin E concentration is consistently low (less than 1 μg/ml). Cerebrospinal fluid analysis has been performed in horses with EMND and demonstrated elevated immunoglobulin G concentrations in approximately 50% of cases. Intrathecal production of immunoglobulin G also occurs in ALS; however, in both diseases this is considered a secondary effect of the disease process rather than a cause. The albumin quotient was normal in most horses examined, indicative of normal blood-brain barrier function.[2]

Electromyography of cervical, facial, triceps, rear limb, and tail head muscles may be useful in acute cases.[1,28] To eliminate motion artifacts, one can sedate horses or place them under general or caudal epidural anesthesia.[28]

However, the electromyographic changes, which include positive sharp waves and fibrillation potentials, may be difficult to evaluate because they are expected in any peripheral nerve disease, myopathy, or myositis.[1,6,28]

In some horses with EMND the glucose absorption test has been found to be abnormal; however, histopathologic examination of the small intestine has failed to identify lesions. The plasma glucose concentration increases only by 40% following 1 g/kg of 20% glucose administered orally, but relatively normal peak concentrations occur after 0.5 g/kg xylose administration (18 to 25 mg/dl). An abnormality in intestinal glucose transport has been identified in vitro.[6,8,9] The clinical significance of this finding is unknown.

More invasive diagnostic tests to confirm the tentative ante mortem diagnosis of EMND are the examination of muscle and nerve biopsies. A biopsy of the sacrocaudalis dorsalis muscle is easy to obtain in a standing horse, and microscopic examination of this muscle may reveal changes consistent with denervation muscle atrophy and 648
scattered muscle necrosis. This test has a sensitivity of approximately 90%. One should place the muscle biopsy 649
sample on a tongue depressor in 10% formalin to prevent contracture artifact.[18] Examination of a biopsy of the ventral branch of the spinal accessory nerve may be more sensitive in chronic cases. Horses generally need to be anesthetized for one to obtain a biopsy from this nerve. Similar as with muscle biopsies, nerve biopsies must be placed on a tongue depressor and in 10% formalin or another fixative suitable for electron microscopy. An experienced neuropathologist should examine nerve biopsies carefully; samples may reveal only evidence of smaller Büngner's bands (columns of proliferated Schwann cells).[12,29]

The definitive diagnosis is based on postmortem examination of spinal cord, brainstem, nucleus ambiguus, and skeletal muscle. The most important differential diagnoses that one should consider are laminitis, rhabdomyolysis, and colic. Other diseases that may cause similar signs are botulism, equine protozoal myeloencephalitis, polysaccharide storage myopathy, iliac thrombosis, equine grass sickness, and lead toxicosis.[8,9,30]

10.16.5 Treatment and Prevention

Currently, no treatment for EMND has been proved efficacious. In acute cases an antiinflammatory dose of corticosteroids or nonspecific antioxidant treatment with dimethyl sulfoxide may be beneficial. The only recommended treatment is based on the idea that this disorder is caused by oxidative injury and on the fact that horses with EMND consistently have low plasma vitamin E concentrations.

Treatment with vitamin E (5000 to 7000 IU/horse/day) results in an increase of plasma vitamin E concentrations to 2.0 μg/ml or greater after 4 to 6 weeks.[9] This treatment may be beneficial; however, full recovery is unlikely because neuronal death is irreversible.[6,8,9] Treatment with vitamin E has been associated with improvement of clinical signs; however, no published studies examining the effect of treatment exist at this time. Response to treatment is thought to depend on the number of neurons that are damaged versus those that are dead. Currently, no diagnostic modality exists to examine this in live horses.

One should give vitamin E supplements to horses that have limited or no access to green grass or hay for prolonged periods. The recommended dose for supplementation is 2000 IU/day of *dl*-α-tocopherol acetate. Not all commercial feeds or supplements contain required amounts of vitamin E for deficient horses. Periodic monitoring of plasma vitamin E concentrations is recommended in horses that are at risk for developing EMND.[8,9]

10.16.6 Prognosis

The prognosis is poor for return to performance and guarded for life. Although no published investigations exist regarding the survival rate and follow-up of horses with EMND, horses with EMND generally have been shown to follow one of three possible clinical courses.[8,9] Approximately 20% of horses continue to deteriorate, and the severe weakness and excessive recumbency necessitate euthanasia. In approximately 40% of horses, clinical signs appear to stabilize; however, these horses do not regain muscle mass and may develop severe gait abnormalities. Continued clinical abnormalities frequently lead to euthanasia within 1 year of onset of clinical signs. The third group of horses (approximately 40%) show dramatic improvement following treatment with vitamin E, and many may regain a normal muscle mass. These horses may remain stabilized, that is, appear normal, for 1 to 6 years or more; however, many relapse, resulting in euthanasia. In a small number of human beings with ALS, a similar scenario occurs when clinical signs stabilize without progression for years.[13] In horses with EMND the relapse appears associated with return to exercise and may be caused by exercise-induced premature death of remaining neurons.[8,9]

10.17

10.17—Botulism

Stephen M. Reed

649

650

Botulism is a caused by a gram-positive, spore-forming, toxin-producing obligate anaerobic bacteria known as *Clostridium botulinum*.[1–5] This bacteria can survive for prolonged periods because of its ability to form spores. The bacteria are distributed widely in nature and can be found in soil, agricultural products, and marine environments.

The bacteria produce several types of antigenically distinct toxins known as A, B, C1, C2, D, E, F, G, and H. The types A, B, E, F, and G are found in the environment, whereas types C and D are found within the intestinal tract of animals and birds.[3,5,6] The molecular weight of the clostridium toxins is about 150 kd.[3] Botulism is a severe neuroparalytic disease caused by the botulinum toxin. Human disease is caused by types A, B, E, and rarely F.[1]

Several diseases result from botulism and can present in a variety of ways. Forage poisoning usually occurs in adult horses following the ingestion of preformed toxin found in feed material that has been contaminated by bacteria. The toxin is absorbed from the intestine or produced in an infected wound and disseminates by the systemic circulation until it binds to specific receptors where it blocks the release of acetylcholine. The result is usually a descending symmetric paralysis. The contaminated feed material may be grain or roughage (usual). In this form of the disease, B or C toxin has been isolated, although a majority of cases result from type B forage poisoning. In a 1997 paper, a majority of horses were demonstrated to be affected because of ingestion of feed material containing decaying vegetable matter with bacterial proliferation and toxin production rather than because of contamination by decomposing animal carcasses in the feed material.[5] In horses that had disease resulting from type C toxin, the cause was the ingestion of decomposing tissue of animals that contained the bacteria within the lumen of the intestinal tract.[7] A report describes type C1 and C2 toxins resulting in signs of neurotoxicity in one horse.[7,8] The same feed given to horses and cattle has been shown to result in disease in the horses while not affecting the cattle, suggesting a species difference in susceptibility to these toxins.[6,7]

Wound botulism has been demonstrated in horses that resulted from type B *C. botulinum* infection in a wound.[2] The bacteria sporulates under anaerobic conditions, resulting in production and release of the toxin. Published reports have described this type of infection following castration, an injection abscess, an infected umbilicus, and other contaminated wounds.[2,4,5,9] This problem is unique to horses, although a few cases have been described in other species; for example, in human beings following sharing of needles and illicit drug abuse.

650

651

In foals a syndrome referred to as toxicoinfectious botulism, or shaker foal syndrome, occurs.[5,6,10] The disease appears to be a sporadic condition affecting foals from a few days to several months of life[10] and appears to result from type B toxin, which has been found in spores contaminating the soil and which can survive for years. One study demonstrated that a high percentage (94%) of soil samples collected from farms that previously have had affected foals contained type B neurotoxin gene.[11] The foals on these farms are suspected to have ingested contaminated soils, and this may have led to the proliferation of spores within the intestinal tract, toxin production and absorption from the intestinal tract, and disease. A similar condition has been described in human infants fed honey or other food contaminated with botulism spores. In adult horses the intestinal flora appears to have a protective eaffect against the proliferation and absorption of spores and toxin. Diagnosis is difficult and most often is based on typical clinical signs; however, in about 30% of affected foals the toxin may be identified in the feces during an acute clinical episode.[5,11,12]

Most cases of botulism in horses result from type B botulism.[2,3,5–10] Less frequently, cases of type C and A have been recognized. Cases of type D botulism in horses have been suspected in the United States, but no cases have been confirmed at this time. In the United States, type B spores are the type most often found in soils in the mid-Atlantic states, whereas type A spores are identified more typically on the West Coast. One report describes an outbreak of type C botulism resulting from contamination of 200,000 tons of hay cubes by decaying rodent carcasses. Whenever more than one horse on a premise demonstrates clinical signs compatible with botulism, quick analyis of the entire ration and the feeding methodology to determine if contamination has occurred is important. This aggressive approach may prevent additional horses or other animals on the farm from becoming infected. Beginning the investigation with the feed, especially ensilage, is always best because this is the most common

source of toxin. Conditions may be optimal for proliferation of botulism spores and toxin production in improperly prepared hay or hay stored in plastic bags.[7]

10.17.1 Clinical Signs

The clinical signs of botulism in horses are often the same regardless of the source of contamination or the type of toxin, even though one may see subtle differences between toxin types A, B, and C.[5,6,9,10] The onset of sign varies but is usually within 24 hours of exposure, although onset can occur in as short as 12 hours or as long as several days.[1] The incubation period maybe associated with inoculum size, which suggests that the shorter the incubation, the more severe the disease. The disease usually affects motor nerves with high efferent traffic, resulting in weakness, dysphagia, and poor muscle tone. One can detect the lack of normal muscle clinically by evaluating eyelid tone, which often is weak. Affected horses appear to maintain coordination and therefore appear weak but not ataxic. Early in some cases the owners will note prolongation of the time the horse takes to eat its grain or note abdominal discomfort and colic. The time to ingest a small quantity (usually a cup) of grain can be useful as a predictor of whether the horse has botulism. Some horses may have colic, decreased salivation, and occasionally urinary retention resulting from involvement of the cholinergic autonomic nervous system.

Over time horses demonstrate muscle fasciculations, often first in the triceps region, that eventually progress to the entire body and result in recumbency. At first the horse appears to gain strength after lying down for a short time and may return to standing spontaneously or with coaxing. Eventually the horse is unable to rise. Clinical evaluation should include careful examination of the tongue, eyelid and tail tone, and the pupillary light response, which appears sluggish. One will note ptosis of the eyelids. In horses affected for a longer time one may note an abnormal pattern of respiration. Death often results from respiratory failure.[5,6,8]

10.17.2 Differential Diagnosis

The differential diagnosis for horses affected with botulism can be any cause of weakness and dysphagia in horses and should include protozoal myeloencephalitis; equine motor neuron disease; equine herpesvirus (type 1) myeloencephalopathy; rabies; several toxins such as lead, yew, and yellow star thistle; low blood calcium; and hyperkalemic periodic paralysis.[5,6,10] One also should consider less common clinical diseases such as tick paralysis vascular accident or even unusual examples of exercise intolerance.

The diagnosis of botulism is difficult and frequently is based on clinical signs and history. To confirm the diagnosis, one must detect the toxin in feed, serum, gastrointestinal contents, feces, or debris collected from a wound.[4,5,10–13] The toxin is stable in frozen tissues or plasma and can be stored at −20° C for several weeks. The presence of botulism spores in intestinal contents or feed or the presence of an antibody response to *C. botulinum* in a recovered patient are also useful to confirm the diagnosis of botulism in horses.

Methods for detecting botulism toxin include mouse bioassay, enzyme-linked immunosorbent assay (ELISA), 651
polymerase chain reaction test, and use of an optical-based biosenser.[4,8,11–13] The mouse bioassay is sensitive 652
but requires several days to complete and uses many mice. If serum has been collected from a horse in the acute stage of infection, this assay is most accurate. One of the problems associated with this test in serum of horses is that because these animals are so sensitive to botulinum toxin, clinical signs may appear before the toxin reaches threshold levels required for detection. One must add specific antiserum to the test to detect the exact toxin type. Other tests are available, although these are less sensitive than mouse inoculation. The ELISA may be less

specific because of cross-reactivity with other clostridial toxins, but it does have a turnaround time of 24 hours. The polymerase chain reaction test was used to identify an outbreak in Australia caused by type B botulism.[11] The fastest but least sensitive is the optical fiber–based biosenser.[12] The detection of botulism spores from the feces of infected horses has been useful in some outbreaks.[5,8] Compared with normal horses, the detection of spores in the feces is a rare occurrence (16 out of 507 samples). The use of ELISA for the detection of antibody in the serum of horses has been helpful to detect type C and D toxin in horses and cattle.[5]

Another test that may be of benefit is electromyography to identify a decremental response following repetitive stimulation. Although this test has been helpful in human beings, it is rarely helpful in horses. One should suspect a diagnosis of botulism in horses with acute onset of flaccid paralysis, weak or poor eyelid tone, poor tail tone, slow or difficult eating, and dysphagia.

10.17.3 Treatment

Treatment of horses with botulism is usually expensive, time consuming, and often unrewarding. If the disease is recognized early, the prompt use of specific or multivalent antiserum may be helpful. If the disease is slowly progressive, administering 200 ml of antiserum (30,000 IU) to foals or 500 ml (70,000 IU) to an adult horse may be beneficial. Otherwise, nonspecific therapy such as nursing care, tube feeding, sedation to reduce muscle activity, antimicrobial agents, and laxatives may help. One possibly may assist horses with difficulty breathing by using mechanical ventilation.[2,5,6,8,10]

Prognosis is poor with botulism, although for horses that are still standing and can be given antiserum, the prognosis may approach 70%.[4] The shorter the time the horse is recumbent and the sooner it can swallow, the better the prognosis. In horses that do survive, the recovery is complete. The disease is preventable by vaccination using type B toxoid. This vaccine was developed to prevent disease in newborn foals and is given to pregnant mares. The usual schedule is three doses at 1-month intervals with revaccination 6 weeks before foaling annually.[5,6,10]

10.18

10.18—Equine Grass Sickness (Equine Dysautonomia)

Yvette S. Nout

Equine grass sickness (EGS) is an acquired degenerative polyneuropathy that predominantly affects the neurons of 652
the autonomic and enteric nervous system. The disease was recognized first in Scotland in 1909[1] and since then has 653
been reported in other parts of England, continental Europe, and Australia.[2,3] A clinically and histopathologically similar disease, *mal seco,* occurs in Argentina, southern Chile, and the Falkland Islands.[4] So far the disease has not been recognized in northern America.

The disease affects postganglionic parasympathetic and sympathetic neurons and is characterized as a dysautonomia. Clinical signs vary, and the severity of EGS is suggested to be related to the extent of neuronal damage. The disease occurs sporadically and is often fatal. Although EGS has been studied extensively, the cause of the disease remains unknown.

10.18.1

Clinical Signs

Equine grass sickness has been reported in other equids such as the Przewalski's horse, zebra, donkey, and pony but primarily occurs in young, mature horses that have access to pasture. Horses with EGS are generally between 2 and 12 years of age and horses between the ages of 3 and 5 years are at greatest risk for developing the disease. No breed or gender predilection to the disease is apparent.[3]

Acute, subacute, and chronic forms of EGS are recognized, of which clinical signs overlap from one form to the other.[5,6] Most horses are depressed and dysphagic. The dysphagia is caused by cranial nerve involvement and is recognized by drooling of saliva, feed material in the nares, impacted feed material in the buccal pouches, and difficulty drinking.

10.18.1.1

ACUTE FORM

Clinical signs are related to acute onset of gastrointestinal ileus. The course of disease is generally less than 48 hours. Signs of abdominal pain may be severe and are caused by gastric and small intestinal distention. Affected horses are hypovolemic, and the reduced circulating volume may cause death from cardiac failure. Other clinical signs are generalized or patchy sweating, fine muscular fasciculations, pyrexia, severe dysphagia, and bilateral ptosis. Examination per rectum reveals small intestinal distention and often a mild

secondary impaction of the large colon. One can obtain a large quantity of reflux following nasogastric intubation.

10.18.1.2 SUBACUTE FORM

The course of disease is 3 to 7 days, and clinical signs are less severe than in acute EGS. Horses with subacute EGS do not develop gastric or small intestinal distention but develop large colon impactions. These horses have a characteristic “tucked-up” stance. Clinical signs include intermittent colic and patchy sweating. These horses often have rhinitis sicca.

10.18.1.3 CHRONIC FORM

The course of the disease is weeks to months. Cachexia is the most prominent clinical abnormality in horses with chronic EGS. The entire gastrointestinal tract is empty in these horses, and they usually have rhinitis sicca characterized by accumulation of mucopurulent material in the nasal passages. Other clinical signs in animals with chronic EGS are sweating, muscle tremors, gait abnormalities (short-strided), leaning against walls, base-narrow stance, snoring, pica, and penile prolapse. In a later stage, one may observe coat abnormalities such as areas of piloerection, growth of a long coat, and pallor of the coat.

10.18.2 Pathologic Findings

Gross necropsy findings in acute EGS are consistent with gastrointestinal ileus. A large fluid-filled stomach and distended small intestine are present. Secondary impacted ingesta is often present in the large colon and cecum. Splenomegaly and erosions of the esophageal mucosa are other findings in acute EGS. Gross necropsy findings in subacute EGS are less severe and include colonic impaction.[2,5] One may find inspissated mucous in the lumen of the small colon and rectum and evidence of intraluminal hemorrhage such as inspissated blood or black feces. In horses with subacute and chronic EGS, one may find rhinitis sicca.

Neuronal lesions are most severe in the autonomic ganglia (cranial cervical, stellate, celiacomesenteric) and enteric nerves. One finds less severe lesions in some brainstem nuclei and parts of the spinal cord.[2,5–7] Changes detected in affected neurons are degenerative changes and include chromatolysis, loss of Nissl's substance, loss of the nucleus, spheroid formation, neuronal swelling, and an increase in the number of lysosomes and mitochondria.[2,5,6] Loss of a recognizable Golgi apparatus appears to be an early neuropathologic event in EGS.[5]

A recent study has demonstrated a reduction of neuropeptide expression in nasal mucosal innervation in horses with EGS.[8] This is suggested to underlie the presentation of rhinitis sicca seen in this disorder.

Similarly to other neurodegenerative diseases, one finds a specific anatomic distribution of neuropathologic conditions in EGS, which supports the hypothesis of a common factor sensitizing the neurons to specific insults. As in EGS, multiple system involvement is a common feature in human neurodegenerative disorders. The central pathologic condition in EGS appears to be specific and repeatable, consistent with findings in primary dysautonomias in other species. However, in EGS, one does not see the increasing severity of pathologic findings and severity of clinical signs with increased duration of disease consistently as is seen in classical 653
neurodegenerative diseases in EGS. Moreover, the decrease in severity of pathologic conditions of the brain with 654
increased duration of disease may suggest a healing process from the initial insult. The association between central neuronal pathologic findings and severity of clinical disease is unclear. In one study, increased neuronal

pathologic findings were observed in milder clinical cases (chronic EGS),[7] which contrasts to another study that demonstrated increased neuronal pathologic findings in acute cases of EGS.[9]

10.18.3 Pathophysiology

Clinical signs are related to the damage of the autonomic nervous system. The most severe lesions are found in the myenteric and submucosal plexuses of the ileum and less severe changes occur in the celiacomesenteric ganglion. The altered autonomic activity results in cessation or decrease of intestinal peristalsis and subsequently leads to the development of ileus and colonic impaction. The dysphagia in most cases of EGS is caused by cranial nerve or brainstem involvement.[5] Based on epidemiologic and pathologic findings in horses with EGS, an unidentified neurotoxin is implicated as the causative agent of the disease; however, because of the complexity of the disease, multiple factors are suspected to be involved in the pathogenesis of EGS.[2,3,5]

Multiple experimental studies have failed to identify the causative agent(s) of EGS. Risk factors for developing the disease have been identified, however. Young horses between 3 and 5 years of age are at greatest risk for developing EGS.[3] Older horses have been suggested to be resistant to EGS, perhaps following nonfatal exposure to the causative agent. Moreover, horses that had been in contact with cases of EGS were 10 times less likely to develop the disease.[10] Similarly, transfer of maternal antibodies against this causative agent may explain the fact that EGS has not been reported in horses younger than 6 months. Horses that are kept solely at pasture are at increased risk of developing EGS; however, the disease has been reported in stabled horses and in horses that had no access to grass at all. The type of pasture or the type of supplementary feeds do not appear to be associated with the development of EGS. Horses that have been on the premises for less than 2 months and horses that have been moved recently to a different pasture are at increased risk of developing EGS. Horses are more likely to be affected with EGS when they are housed on premises that have experienced the disease previously. Although cases of EGS can occur year-round, the incidence of EGS consistently has been found to be greatest during the spring months, particularly if a period of warm weather is followed by a period of wet weather.

Paravertebral ganglionic damage exceeds and occurs earlier than prevertebral ganglionic damage. The putative neurotoxin is suggested to be ingested and initiates damage in the enteric plexuses, which leads to immediate functional deficits seen in the acute form of EGS.[5] Functional lesions precede structural lesions caused by secondary retrograde axonal degeneration. In chronic EGS, less initial enteric nerve damage occurs, and subsequently fewer secondary prevertebral ganglionic lesions occur. Consequently, the body has more time to develop functional and structural compensatory mechanisms. The less severe damage to the celiacomesenteric ganglion compared with the damage in the paravertebral ganglia is suggested to be caused by hematogenous spread of an ingested neurotoxin.

Currently, toxicoinfection with *Clostidium botulinum* type C is being investigated as a cause of the disease.[11–13] This organism grows and produces toxin in the gastrointestinal tract. The role of this organism in the cause of EGS is supported by the fact that type C botulinum neurotoxin has been detected in the gastrointestinal tract of 67% of horses with acute and 74% of horses with chronic EGS compared with 10% of control horses.[14] Moreover, horses with EGS were found to have lower immunoglobulin G concentrations to the surface antigens of *C. botulinum* type C and to type C botulinum neurotoxin. An association between antibody concentration and form of EGS was not demonstrated, but horses that had been exposed to other horses with EGS or that had been grazing on pasture where the disease had occurred previously had significantly higher antibody concentrations to these antigens.[11] These findings may indicate the development of a protective immune response against the

putative neurotoxin. More recently it has been demonstrated that fresh grass may contain botulinum neurotoxin, and this supports the hypothesis that EGS may be a form of soil-borne botulism in horses.[12] It is suggested that natural-occurring biofilms may protect bacteria and chance their survival; however, further research in the areas of etiology, pathogenesis, treatment, and prevention of EGS is necessary.

The sulfur amino acid depletion in horses with EGS has been suggested to contribute to the pathogenesis of this disease through the increase of oxidative neuronal death; however, this has not been proven.[15] A further study found no evidence of systemic macromolecular oxidative damage in horses with EGS.[16] Mycotoxin toxicity also has been implicated as a cause for EGS,[13] and low sulfur amino acid concentrations may enhance the toxicity of mycotoxins.

10.18.4 Diagnosis

No noninvasive definitive test exists to obtain an antemortem diagnosis of EGS. Serum biochemical and hematologic examinations do not reveal specific changes in horses with EGS. Plasma amino acid analysis in 654
horses with acute EGS demonstrated a significant increase in plasma taurine concentration and a significant 655
decrease in plasma cysteine, arginine, citrulline, histidine, isoleucine, leucine, methionine, threonine, tyrosine, and valine concentrations. In horses with subacute and chronic EGS, these changes were less significant and the plasma amino acid profile normalized. Although one cannot use the amino acid analysis as a definitive test for EGS because of overlap in individual amino acid concentrations for control horses, horses with EGS, and horses grazed with EGS-affected horses, the test may have value as an additional diagnostic aid, for adequate plasma cysteine concentrations (greater than 17 μmol/L) may exclude EGS.[15] Most horses with EGS and healthy co-grazed horses had significantly decreased plasma sulfur amino acid (cysteine and methionine) concentrations compared with healthy control animals.

When watching a horse eat, one may notice signs of abnormal esophageal function such as esophageal spasm and reverse peristalsis. Contrast radiography and endoscopy of the esophagus may reveal abnormalities such as megaesophagus and esophageal erosions.[6]

Examination of an ileal biopsy, collected via laparotomy, is the only method to confirm EGS ante mortem.[18] The neuronal degeneration is present in the enteric plexuses from the esophagus to the rectum, but the most severe changes are present in the terminal ileum. Examination of a rectal mucosal biopsy is specific but not sensitive for EGS.

The most important differential diagnoses for acute EGS are a small intestinal strangulating lesion and duodenitis–proximal jejunitis. Clinical signs and neuronal lesions in chronic equine motor neuron disease and chronic EGS may be similar, and these similarities have led to the speculation that these two diseases are related.[19] Further examination, however, reveals important differences such as the fact that equine motor neuron disease occurs in older horses that have not had access to pasture, and EGS occurs in young horses with access to pasture. Equine grass sickness sometimes occurs along with equine motor neuron disease.[2,19]

10.18.5 Treatment and Prevention

No effective cure exists for EGS. Horses with acute EGS may respond initially to gastric decompression and intravenous fluid therapy. Management of horses with chronic EGS includes nursing care and the use of the prokinetic drug cisapride and the appetite stimulant diazepam.[6]

10.18.6 Prognosis

Equine grass sickness is usually fatal. The case fatality rate for acute and subacute cases is 100%. If horses with acute EGS are not euthanatized within 48 hours, they die from circulatory failure or gastric rupture. Horses with subacute grass sickness usually are euthanatized within 7 days.[7] Horses with chronic EGS often are euthanatized because of weakness and emaciation; however, when given appropriate care at a referral hospital, approximately 50% of horse may survive.[6] Survivors may return to work, but some display residual abnormalities such as mild dysphagia, sweating, and coat changes.

10.19 10.19—Lyme Disease in Horses

Stephen M. Reed

Ramiro Toribio

655

656

Lyme disease is the most common vector-borne infectious disease in human beings in the United States. Initially recognized in the mid-1970s in Lyme, Connecticut, as the cause of unexplained rheumatoid arthritis in children, the causative agent of Lyme disease was discovered to be a spirochete, *Borrelia burgdorferi*. In addition to human beings, Lyme disease affects domestic animals such as dogs, cats, cattle, and horses.[1–3]

Human beings and animals acquire Lyme disease by transmission of *B. burgdorferi* through the bite of an infected tick. In the eastern and midwestern United States the vector is the black-legged tick or deer tick, *Ixodes scapularis* (formerly known as *I. dammini*), whereas in the western United States the vector is the western black-legged tick, *I. pacificus*. Not all ticks are infected with the spirochete, and infection varies by tick species and geographic region. These ticks have a 2-year, three-stage life cycle and feed once during each stage.[4] The larvae hatch in the spring and summer and are usually noninfective because transovarial transmission is rare.[5] The tick may become infected at any stage of the life cycle by feeding on small mammalian hosts, typically the white-footed mouse *(Peromyscus leucopus),* which is a natural host for the spirochete. The nymphal stage emerges the next spring and is most likely to transmit the disease because it is small, difficult to see, and engorges faster; engorgement is necessary to transmit *B. burgdorferi*. Once the tick has engorged, *B. burgdorferi* is transmitted to the host via lymphatics or blood. The stage of the life cycle responsible for transmitting Lyme disease in horses is unknown.

10.19.1 Epidemiology

In endemic areas of the northeast and midwestern United States, approximately 20% of nymphal stages and 30% to 40% of adult stages of *I. scapularis* are infected with *B. burgdorferi*. In contrast, *I. pacificus* often feeds on lizards that are poor reservoirs for *B. burgdorferi,* and only 1% to 3% of these ticks, including the nymphal stages, are infected with the spirochete.[5] This difference in the number of infected ticks may explain the difference in the prevalence of Lyme borreliosis between eastern and western United States. Seroprevalence is high in the northeastern United States but is not known for other parts of the country.[3] The apparent increasing incidence of disease in human beings and animals may result from an increased deer population, increased number of ixodid ticks, expansion of human and horse populations into previously rural woodland areas, or increased recognition of the disease manifestations.

The disease has a seasonal prevalence and is most common in spring, summer, and fall with a peak incidence in June and July. In some climates such as California, ticks may be active year-round. The organism is maintained in a complex life cycle of small wild mammals and immature stages of the black-legged tick. Larval and

nymphal stages of the tick acquire the infection when they feed on infected mice. Deer are not a reservoir for Lyme disease but rather a host for the adult stages of the tick.

10.19.2 Clinical Signs

Clinical signs associated with *B. burgdorferi* in horses, as in human beings, are often nonspecific and involve multiple body systems. In human beings, clinical signs frequently include annular rash, myalgia, aseptic meningitis, arthritis, and seventh cranial nerve palsy.[5] The disease usually begins as a skin rash and often progresses to involve joints and the nervous and cardiac systems but may involve other body systems as well. In human beings the skin rash may be slowly progressive and sometimes may take up to 1 month before becoming apparent.

In horses, typical clinical signs of Lyme borreliosis include chronic weight loss, sporadic lameness, laminitis, low-grade fever, swollen joints, muscle tenderness, and anterior uveitis. Some horses may demonstrate clinical illness and depression and may go off feed in a short time. The bacteria may enter the central nervous system within a short time following exposure. Chronic arthritis may develop as a result of autoimmune mechanisms, although this is not fully proved.

10.19.3 Diagnosis

The diagnosis of Lyme disease is often difficult. History of tick exposure or living in a Lyme endemic area are helpful and when combined with the identification of clinical signs along with elimination of other diseases allows a presumptive diagnosis. Examination of blood work for other diseases may be more beneficial than a positive blood test for Lyme, although one should complete such a test as well. In human beings an early increase in serum immunoglobulin M often occurs. Response to therapy also helps to support a presumptive diagnosis of Lyme disease. Diagnosis of Lyme disease in horses is difficult,[6] and in many cases one bases a
presumptive diagnosis on history, clinical signs, and response to antibiotic therapy in an animal with probable 656
cause to be infected (i.e., possible exposure). In human beings the skin lesions are obvious. Blood tests are of 657
limited value, although enzyme-linked immunosorbent assay and Western blot testing on blood from suspect animals has been reported.[1,2] One may test samples of joint fluid, cerebrospinal fluid, and tissues from affected patients for presence of organisms.

10.19.4 Pathogenesis

B. burgdorferi organisms are capable of nonspecifically activating monocytes, macrophages, and synovial lining cells, as well as natural killer cells, B cells, and complement leading to production of host proinflammatory mediators. These proinflammatory mediators seem to localize in joints, leading to a chronic arthritis and lameness. In addition, *B. burgdorferi* has developed strategies to interact with the mammalian host, including adhesion to host cells and components of the extracellular matrix such as fibrinectin, β_3 integrins, and glycosaminoglycans.

10.19.5 Treatment and Prevention

Many horses are treated annually for a presumptive diagnosis of Lyme disease. Treatment can be a prolonged course of antibiotic treatment with tetracycline, doxycycline, and ceftiofur. One may give medications by oral,

intravenous, or intramuscular routes and expect a response within 2 to 4 days. In some horses the clinical signs may show an initial worsening as a response to toxins released following death of the organisms.

Currently, no licensed vaccine is available to prevent Lyme disease in horses, although several vaccines are on the market at this time and a human vaccine is being developed. Aids to prevention include daily grooming with removal of ticks, along with the use of tick repellents that contain permethrin. One should apply tick repellents to the head, neck, legs, abdomen, and under the tail. Keeping pastures mowed and removing brush and woodpiles makes the environment less hospitable for rodents, which in turn decreases the tick population.

10.20 10.20—Head Shaking

Robert H. Mealey

10.20.1 Clinical Signs

Head shaking is a widely recognized disorder characterized by persistent or intermittent, spontaneous, and frequently repetitive vertical, horizontal, or rotary movements of the head and neck.[1] The affected horse shakes, jerks, or flicks its head uncontrollably in the absence of obvious physical stimuli, and the condition can be severe enough to render the horse unusable and dangerous.[2–5] Head shaking often is accompanied by snorting and sneezing, and many horses rub their noses on stationary objects or on the ground while moving. In addition to shaking the head up and down, flipping the upper lip, or shaking the head side to side, horses also may act as if a bee has flown up the nostril or may strike at the face with the forelimbs.[2,6,7] Head-shaking horses also may exhibit avoidance behavior, with low head carriage, corner seeking, and nostril clamping.[1,8] To characterize the severity of clinical signs, a grading system of 1 to 5 has been described, with grade 1 being a rideable horse with intermittent and mild signs (facial muscle twitching) and grade 5 being an unrideable, uncontrollable, dangerous horse with bizarre behavior patterns.[1] Clinical signs are usually worse during exercise; however, head shaking can affect horses at rest.[1–5,7] Mean age of onset is typically 7 to 9 years, and Thoroughbreds and geldings appear to be overrepresented in some studies.[2,3,6] Head shaking can be seasonal or nonseasonal. Early literature suggested an increased incidence of head shaking during the warmer months of the year,[5] and a later study 657

indicated that the peak periods of onset were spring and early summer.[3] Recent studies have found that 64%[6] and 59%[2] of head-shaking horses are affected seasonally, with the majority developing signs in the spring or early summer. 658

10.20.2 Pathogenesis

Early work suggested 58 possible causes for head shaking, including 2 that have received considerable attention recently: photophobia and trigeminal neuralgia.[9] Other reported and suggested causes include behavioral resentment to rider-induced head and neck flexion, exercise-induced hypoxia, ear mites, cranial nerve dysfunction, otitis media or otitis interna, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis, vasomotor rhinitis, allergic rhinitis, *Trombicula autumnalis* (harvest mite) larval infestation, maxillary osteoma, and equine protozoal myeloencephalitis.[3,4,9–14] A study of 100 head-shaking horses revealed a potential specific cause in only 11 horses, and elimination of the abnormality resulted in resolution of the head shaking in only 2 of them.[3] Idiopathic head shaking has been used to describe the majority of cases in which no specific underlying cause is found, and necropsy results in these horses reveal no lesions.

The clinical signs exhibited by most head-shaking horses now generally are thought to result from sharp, electric-like, burning pain involving the trigeminal nerve.[1,2] Trigeminal nerve involvement is supported by the observations that some horses improve after blocking the infraorbital nerve (part of the maxillary branch),[15,16] and that most horses improve after blocking the posterior ethmoidal nerve (part of the ophthalmic branch).[1] Horses that head shake in response to light stimulation have been described as photic head shakers.[8] Most of these horses are affected seasonally (spring and summer), improve at night or when brought indoors, and improve when blindfolded or when gray lenses are placed over their eyes. Photic head shaking is hypothesized to be caused by optic-trigeminal summation (stimulation of the optic nerve that results in referred sensation to parts of the nose innervated by the trigeminal nerve), a mechanism similar to that proposed for photic sneezing in human beings.[2,8] Many features of head shaking in the horse are similar to trigeminal neuralgia in human beings, a severe chronic pain syndrome characterized by dramatic, brief stabbing or electric shock–like pain paroxysms felt in one or more divisions of the trigeminal distribution, spontaneously or on gentle tactile stimulation of a trigger point on the face or oral cavity. The disease is associated with microvascular compression and pathologic changes in the trigeminal root and trigeminal ganglion.[17] The basic underlying cause of head shaking in the horse may be trigeminal neuralgia,[1] and recent work suggests a degenerative disorder of the brainstem nucleus of the trigeminal nerve (D.C. Knottenbelt, personal communication). The trigeminal nerve is postulated to be hypersensitive and to fire in response to a variety of trigger factors including wind, airway turbulence, increased blood flow, pollen, dust, warmth, cold, insects, allergies, or other irritations. These trigger factors appear to act intranasally in many horses but could act in any trigeminal sensory region.[1]

10.20.3 Diagnosis and Treatment

One should perform a complete physical examination, including neurologic, dental, ophthalmic, and otoscopic examinations to rule out potential underlying causes. Other diagnostics could include endoscopy of the nasal passages, pharynx, and guttural pouches; radiography of the skull and cervical spine; complete blood count; and serum biochemistry profile. These examinations reveal no abnormalities in most cases. A recent survey suggests that one should consider idiopathic head shaking if two of the following three clinical signs are present: vertical flipping of the head, acting as if an insect has flown up the nostril, or rubbing the muzzle on objects.[2] For photic

head-shaking horses, clinical signs should improve following blindfolding or after placement of a mask shielding the eyes from the sun.

Cyproheptadine, an antihistamine (histamine$_1$) and serotonin antagonist with anticholinergic effects, has been used (0.3 mg/kg orally b.i.d.) to treat head-shaking horses, resulting in improvement in 5 of 7 horses in one study[8] and 43 of 61 horses in another.[2] Horses that respond do so within 1 week, and some may respond within 24 hours. Although the mechanism for efficacy of cyproheptadine in these cases is unknown, blocking of serotonin-mediated pain sensation could be involved.[8] Other investigators have found cyproheptadine alone to be ineffective, but the addition of carbamazepine (4 to 8 mg/kg orally t.i.d. or q.i.d.) resulted in 80% to 100% improvement in seven of nine cases, with horses responding within 3 to 4 days.[1] Carbamazepine is a sodium channel-blocking antiepileptic drug and is the drug of choice for treating trigeminal neuralgia in human beings.[18] Carbamazepine alone was reported to be effective in head shaking horses, but results were unpredictable.[1] The elimination half-life of carbamazepine in the horse is less than 2 hours, making sustaining therapeutic concentrations difficult; the drug is therefore of more benefit diagnostically than therapeutically in head-shaking horses (D.C. Knottenbelt, personal communication). Other medications and therapies including nonsteroidal antiinflammatory drugs, corticosteroids, antihistamines, acupuncture, chiropractic manipulation, homeopathy, and feed supplements are generally ineffective in most horses.[2,19] 658

659

Diagnostic blockade of trigeminal nerve branches can be useful for identifying trigger points in head-shaking horses. Blockade of the infraorbital nerve may improve some horses and might identify candidates for infraorbital neurectomy.[15,16] However, results of infraorbital blockade and infraorbital neurectomy do not correlate, and because of neuroma formation, self-trauma, and low success rate, infraorbital neurectomy is not a recommended procedure.[15] A high percentage of horses improve after blockade of the posterior ethmoidal nerve, and sclerosis of this nerve results in temporary improvement in some horses.[1]

Therapies aimed at decreasing the response to trigger factors can be effective and include tinted contact lenses; face masks or hoods that block sunlight, wind, insects, dust, etc., with mesh or dark eye cups; and nose nets.[1,2,8,19,20] A recent owner survey found that nose nets that cover the nostrils with mesh and include a draw string or elastic band that applies pressure to the upper lip resulted in some improvement in 70% of head-shaking horses, and that 70% or more improvement occurred in about 30% of the horses.[20] Finally, permanent tracheostomy is effective in some horses,[1,4] presumably because airflow then bypasses the nasal cavity where the majority of trigger factors are thought to act.[1]

10.21

10.21—Verminous Encephalomyelitis

Eduard Jose-Cunilleras

Aberrant migration of helminth and fly larvae through the central nervous system (CNS) of horses and donkeys is a rare but important cause of severe neurologic disease. Parasites that have been reported to affect the brain and spinal cord of equids include rhabditid nematodes (*Halicephalobus [Micronema] deletrix* [synonym *H. gingivalis*]), strongyloid nematodes (*Strongylus vulgaris, S. equinus,* and *Angiostrongylus cantonensis)*, spiruroid nematodes *(Draschia megastoma),* filarid nematodes (*Setaria digitata* and other *Setaria* spp.), and warble fly larvae (*Hypoderma* spp.).

Antemortem diagnosis is often impossible; however, a high index of suspicion may be warranted for certain clinical signs (acute onset or rapidly progressive asymmetric, focal, or multifocal brain or spinal cord signs) and changes in cerebrospinal fluid (CSF) analysis; in which case the treatment regimen should include specific

antiparasitic drugs (e.g., fenbendazole) in addition to the more routinely used symptomatic and antiinflammatory treatments (nonsteroidal antiinflammatory drugs, dimethyl sulfoxide, corticosteroids, antiprotozoal drugs, etc.). 659

660

10.21.1 Causes

10.21.1.1 *HALICEPHALOBUS (MICRONEMA) DELETRIX (H. GINGIVALIS)*

Halicephalobus deletrix is synonymous with *H. gingivalis,* the latter being the most recent terminology.[1] The parasite was referred to as *Micronema deletrix* until 1970s and 1980s.

The life cycle of *Halicephalobus* nematodes is unknown. This small roundworm generally is considered a saprophytic organism that occasionally acts as a facultative parasite in horses and human beings. The likely route of entry is through nasal and oral mucosa followed by possible hematogenous spread to organs with high vascularization such as the brain, spinal cord, and kidneys. *H. deletrix* recently has been shown to be transmitted from a mare to her foal because of mammary infestation.[2]

Organs affected by migration of *Halicephalobus* include the brain, spinal cord, nasal and oral cavities, pituitary gland, and kidneys and less commonly the lymph nodes, heart, lungs, stomach, liver, and bones.[3,4] Organisms affecting the CNS have been reported to have a predilection for the basilar, pituitary region of the brainstem.[5] Characteristic histopathologic lesions in the CNS include malacia, granulomatous and lymphohistiocytic inflammatory infiltration, meningitis, and vasculitis in addition to identification of the nematodes. Other clinical signs include oral and nasal granulomata, renal involvement (*H. deletrix* is visible in the urine), granulomatous osteomyelitis,[6] and granulomatous chorioretinitis.[7]

Most of the cases of *Halicephalobus* encephalomyelitis in adult horses reported in the literature during the last 30 years describe simultaneous renal granulomatous lesions encapsulating the nematodes (Table 10.21-1). Granulomata within or adjacent to the renal parenchyma were observed on postmortem examination in 13 of 16 horses with neurologic disease, and of the other 3, in 1 case lesions were confined to the sacral spinal cord and cauda equina and in another case only the skull and brain was examined at postmortem. In contrast, all 3 cases reported to date in foals showed no renal involvement but did show pulmonary granulomata.[2,5]

10.21.1.2 *STRONGYLUS VULGARIS, S. EQUINUS*, AND *ANGIOSTRONGYLUS CANTONENSIS*

Aberrant strongyle larval migration is a much less common cause of neurologic signs because of routine broad-spectrum antiparasitic treatment with ivermectin and moxidectin. The pathogenic mechanisms described for strongyle encephalomyelitis include aberrantly migrating fourth- and fifth-stage larvae in the intima of the aorta or left ventricle, which causes endothelial damage, stimulates the clotting cascade, and results in formation of a thrombus that often contains the parasitic larva.[20] Lesions are generally asymmetric because of random migration in the brain, although migration along the spinal cord has been reported in a donkey.[21]

10.21.1.3 *DRASCHIA MEGASTOMA*

Adult *D. megastoma* worms are found in the stomach of equids, and they cause mucosal granulomatous masses and mild chronic gastritis. The life cycle of *Draschia* is indirect because the organism uses flies as the intermediate host. Eggs and larvae are released into the gastric lumen, and the first larval stage passes in the feces and is ingested by fly larvae of the genus *Musca* in which *Draschia* organisms develop to infective larvae. Finally, horses become infected when the third larval stage is deposited on the host by adult flies. Infective larvae that are ingested and reach the stomach develop into adults and complete the life cycle. Larvae deposited in damaged skin result in local inflammation and development of extensive granulation tissue, which is the typical lesion of cutaneous habronemiasis.

Stray *D. megastoma* larvae may be found anywhere throughout the body, and a case has been reported of *D. megastoma* migration in the brainstem of a horse in southern United States resulting in asymmetric brainstem disease.[22]

10.21.1.4 *SETARIA* SPP.

Infestation with the filarial nematode *Setaria* is common in the abdominal cavity of ungulates where the organism does not cause significant clinical effects. *S. labiato-papillosa* is found in cattle, and *S. equina* is found in horses. Microfilariae gain access to peripheral circulation and then are transmitted to other potential hosts via mosquitoes. In a postmortem examination study of 305 horses in Japan, *S. equina* was recovered from 66 of those horses (~22%).

The cattle parasite *S. digitata* occurs only in Asia, and infestation in unnatural hosts (horses, sheep, goats, camel, and human beings) has been associated with cerebrospinal nematodiasis. This condition can be enzootic in India, Burma, and Sri Lanka, and is called “Kumri” (weak back) and has a seasonal occurrence, usually during the fly season (late summer and fall).[27]

Two cases of aberrant *S. digitata* CNS migration have been reported in Japanese racehorses, and one case of *Setaria* larval migration in the brainstem and cervical spinal cord has been reported in a 12-year-old Quarter Horse mare in the midwestern United States.[19,28]

10.21.1.5 *ANGIOSTRONGYLUS CANTONENSIS*

Adult parasites are found in the right ventricle and pulmonary artery of rats. The pulmonary circulation carries 660
eggs released by adult worms to the alveoli, where the first larval stage develops and migrates up the trachea, 662
is swallowed, and passes in feces. Snails and slugs are intermediate hosts, and ingestion of the snail results in ingestion of the infective larvae that migrate through CNS, and finally, the larvae reach the heart via the circulation.

TABLE 10.21-1 Signalment, Organism Identified, Clinical Signs, and Organs Affected in Cases of Verminous Encephalomyelitis

PLR, Pulpillary light response.

Aberrant CNS migration of *A. cantonensis* larvae has been reported in two foals with tetraparesis in Australia,[23] and aberrant migration is a recognized cause of eosinophilic meningoencephalitis in human beings and dogs.[29]

10.21.1.6 *HYPODERMA* SPP.

Cattle are normal hosts of *Hypoderma* spp., but horses are accidental hosts of warble fly larvae. In cattle, 662

Hypoderma larvae penetrate the skin after hatching from eggs attached to hair in the rump and lower legs. 663 These larvae migrate through connective tissues to reach the esophagus, in the case of *H. lineatum*, or to the vertebral canal around epidural fat, in the case of *H. bovis*. Finally, the larvae migrate back to the skin over the back where they create a breathing hole. Cutaneous myiasis is uncommon in horses, and warble fly larvae occasionally may migrate aberrantly into the brain, and tissue damage causing necrosis and hemorrhage is extensive because of the big size of the instars.[24] Instars can enter through large natural foramina such as the foramen magnum, optic foramen, and occasionally intervertebral foramina.

10.21.2 Clinical Signs

Severity and duration of clinical signs vary from mild, transient, and insidious to severe and fatal. In some cases, clinical signs progress over 2 to 4 months with periods of improvement or stabilization.[4,22,30] Variability of clinical signs depends on the number of parasites (thromboembolic shower of *Strongylus vulgaris*), on the size of the migrating organism (*Hypoderma* spp. larvae are large and cause severe necrosis and hemorrhage as they migrate in the CNS parenchyma), and neuroanatomic localization of the lesions. Horses suffering from larval migrations in the brain (*S. vulgaris, Halicephalobus deletrix, D. megastoma,* and *Hypoderma* spp.) may display head tilt, circling, recumbency, blindness, hyperesthesia, stiff neck, ataxia, head pressing, recumbency, seizures, and coma. In those cases in which larvae cause lesions in the spinal cord (*S. vulgaris, Halicephalobus deletrix, Setaria* spp., *A. cantonensis*), clinical signs may include focal or multifocal asymmetric ataxia, weakness, dog-sitting posture caused by paraparesis, increased patellar reflexes, atonic bladder, poor tail tone, and poor rectal tone with impaction of feces (see Table 10.21-1). Recently, a case of cauda equine neuritis has been reported that was caused by *H. gingivalis* migration in the sacral spinal cord and cauda equina nerves.[14]

10.21.2.1 Differential Diagnosis

One should consider verminous encephalomyelitis in all cases of acute or progressive asymmetric disease of the spinal cord, cerebrum, cerebellum, or brainstem. If brain involvement is evident without other localizing signs, the differential diagnosis list may include equine togaviral encephalomyelitis, rabies, equine protozoal myelitis (EPM), trauma, cerebral abscess or basilar epidural empyema, bacterial meningitis, hepatic encephalopathy, neoplasia, and leukoencephalomalacia. If the neurologic signs are limited to spinal cord involvement, other diseases to include in the differential diagnosis list may be cervical stenotic myelopathy, EPM, equine herpesvirus 1 myeloencephalopathy, trauma, West Nile virus meningoencephalitis, equine degenerative myeloencephalopathy, trauma, spinal osteomyelitis or discospondylitis, vertebral fracture, and neoplasia. If the only signs present are related to cauda equina syndrome, other conditions to consider are polyneuritis equi, sacral or coccygeal fracture, EPM, equine herpesvirus 1 myeloencephalopathy, sorghum or Sudan grass toxicity, epidural abscess from tail blocking, and neoplasia.

Initial diagnostics should include complete blood count, serum chemistry profile, urinalysis, and CSF collection for cytologic evaluation. In addition, serologic examination and viral isolation and CSF Western blot for EPM may help eliminate several more common viral and protozoal myeloencephalitides. Radiographs of the cervical or lumbosacral spine and myelography may be required to rule out more common causes of spinal cord disease (cervical stenotic myelopathy, trauma, fractures). Although only routinely available at referral hospitals, advanced imaging techniques (e.g., computerized axial tomography and magnetic resonance imaging) may be useful in diagnosing parasitic encephalomyelitis or other conditions with similar clinical signs.

Cerebrospinal fluid analysis in cases of parasitic encephalomyelitis can be normal; however, CSF changes are common and include xanthochromia, increased protein, and neutrophilic and mononuclear pleocytosis, but eosinophils rarely occur (Table 10.21-2). Only in case of *A. cantonensis* were eosinophils the predominant cell type on CSF cytologic examination. In addition, *H. deletrix* eggs are visible on microscopic examination of a CSF sample subjected to cytocentrifugation.[5] Similarly, *H. deletrix* larvae may be visible on microscopic examination of urine sediment or semen in cases of renal and testicular involvement.[4]

Antemortem diagnosis may be possible in those cases in which renal or bony involvement is detected and nematodes are identified in biopsies of the affected tissues.[6] As described previously, renal involvement with granulomatous lesions encapsulating *H. deletrix* worms is observed in most cases of *H. deletrix* encephalomyelitis. Therefore transabdominal renal ultrasound examination and ultrasound-guided biopsy (in those cases with renal lesions present), as well as microscopic examination of urine sediment, may prove useful in cases of acute onset progressive asymmetric neurologic disease, especially if one suspects cerebrospinal nematodiasis caused by *H. deletrix*.

Additionally, a polymerase chain reaction–based diagnostic test has been developed for confirmation of *Setaria* encephalomyelitis in goats, sheep, and horses.[31] This test is based on specific amplification of *Setaria* filarial DNA from a blood sample from the host. 663

TABLE 10.21-2 Cerebrospinal Fluid (CSF) Analysis in Verminous Encephalomyelitis

ORGANISM	WHITE BLOOD CELLS IN CSF	PROTEIN IN CSF	CELLS IN CSF	LARVAE PRESENT IN URINE	REFERENCE
Halicephalobus	2030 cells/μl	89 mg/dl	Mostly PMNs[*]	—	9

Strongylus	Two of 8 ponies had increased white blood cell counts: 42 cells/μl and 1080 cells/μl.	One of 8 ponies had high protein at 175 mg/dl.	—	20	
Strongylus	9988 cells/μl	550 mg/dl	72% N, 14% L, 12% M, 2% E	—	21
Draschia	Normal	Normal	—	—	22
Angiostrongylus	1560 cells/μl	—	1% N, 8% L, 14% M, 77% E	No	23

* PMN, Polymorphonuclear neutrophil leukocytes; N, neutrophils; L, small lymphocytes; M, large mononuclear cells; E, eosinophils; B, basophils.

10.21.3 Pathologic Findings

The gross and histopathologic lesions depend on the parasite involved. Thorough postmortem examination with sectioning and histopathologic examination of all areas of the CNS relevant to the antemortem clinical signs are important to identify migrating parasites. *Strongylus vulgaris* and *Hypoderma* spp. larvae are easy to see, but other nematodes are only visible on microscopic examination. Some reports describe how one may recover and examine whole, fixed nematodes for distinctive morphologic features by centrifugation of formalin solution in which the brain had been fixed.[8,17] Gross examination of other tissues for evidence of *S. vulgaris* thrombi or presence of *Halicephalobus deletrix* granulomatous lesions may help establish a postmortem diagnosis.

On histopathologic examination, one generally sees extensive tissue necrosis with mixed inflammatory response. *H. deletrix* migration in the CNS typically results in histiolymphocytic infiltrates, malacia, glial proliferation, and perivascular lymphocytic cuffing. Migrations of warble fly and *S. vulgaris* larvae result in severe hemorrhage, large malacic tracts, and edema caused by their relative larger size.

10.21.4 Treatment

Treatment of verminous encephalomyelitis in horses is often unrewarding. None of the cases reported in the literature have responded favorably to antiinflammatory drugs and antihelmintics. Only in one case of *H. deletrix* granuloma limited to the prepuce, therapy with ivermectin and diethylcarbamazine was successful.[32] However, numerous cases of cerebrospinal nematodiasis likely respond favorably to antiinflammatory drugs and antihelmintics, but one never reaches a definitive diagnosis because diagnosis requires a postmortem examination.

Therapeutic recommendations depend on the severity, progression, and localization of neurologic signs and on consideration of possible contraindications (e.g., if one suspects bacterial or viral cause, one should avoid using corticosteroids). In cases of acute neurologic disease use of the following antiinflammatory drugs may be warranted: nonsteroidal antiinflammatory drugs such as phenylbutazone (2.2 mg/kg twice daily), flunixin meglumine (1 mg/kg twice daily), or ketoprofen (2 mg/kg twice daily); intravenously administered dimethyl sulfoxide (1 g/kg as a 10% solution once daily for 3 to 5 days); and corticosteroids (dexamethasone at 0.1 to 0.25 mg/kg once daily or prednisolone at 0.2 to 4.4 mg/kg once daily). If one observes cerebral signs, one may administer mannitol (0.25 to 2 g/kg as a 20% solution once daily), or hypertonic saline may be warranted in an attempt to minimize cerebral edema. In countries in which equine protozoal myelitis is known to occur, antiprotozoal treatment is recommended with sulfadiazine (20 mg/kg by mouth twice daily) plus pyrimethamine (1 mg/kg by mouth once daily) or alternatively with ponazuril (5 mg/kg once daily) or diclazuril. 664

665

Specific antiparasitics suggested for treating verminous encephalomyelitis include benzimidazole compounds (oxfendazole, thiabendazole, fenbendazole and mebendazole), diethylcarbamazine and ivermectin for the treatment of nematodes, and organophosphates (trichlorfon and dichlorvos) for the treatment of warble fly larvae. Although ivermectin is effective against most equine parasites, it may not be the best choice because of its delayed method of killing, which may take as long as 10 to 14 days. Some authors have suggested administration of fenbendazole at 50 mg/kg by mouth once daily for 3 days[33,34]; however, specific data on the efficacy of antihelmintics in treating nematode or warble fly larvae migration through the CNS are not available.

11 CHAPTER 11 DISORDERS OF THE SKIN

Christine A. Rees[*]

11.1 Basic Structure and Function of the Skin

The skin is the largest and one of the most important organ systems within the body. Without skin, a human being or animal would die. The functions of the skin are these:

1. An enclosing barrier that prevents water, electrolytes, and macromolecules from being lost and provides internal support for various organs within the body.
2. A storage reservoir for vitamins, fats, carbohydrates, electrolytes, water, proteins, and other materials.
3. A protective barrier against chemicals and physical factors such as heat, cold, microbiologic organisms, and ultraviolet light (melanocytes).
4. A sensory organ for heat, cold, touch, pain, pressure, and itch.
5. A regulator of body temperature through hair coat.
6. A regulator of blood pressure by changes in peripheral vasculature.
7. A producer of keratinized structures such as hair, hooves, horn, and the uppermost layer of the epidermis.
8. A secretory and excretory organ for apocrine and sebaceous glands that includes antimicrobial factors.
9. A provider of flexibility, elasticity, or toughness to allow for shape and form.
10. An immunosurveillance organ through keratinocytes, lymphocytes, and Langerhan's cells.
11. An indicator of general health (e.g., icteric skin can indicate liver dysfunction).[1]

* The authors acknowledge and appreciate the original contributions of Karen A. Moriello, Douglas J. DeBoer, and Susan D. Semrad, whose work has been incorporated into this chapter.

11.2 Gross Anatomy

11.2.1 SKIN

Skin thickness varies from 1 mm to 5 mm depending on the body location. The skin thickness is greatest at the dorsum and the proximal extremities and gets thinner ventrally and distally down the extremities. Skin is thickest on the forehead, dorsal neck, dorsal thorax, and base of the tail. The skin is thinnest on the ears and in the axillary, inguinal, and perianal areas.[2,3]

The skin consists of two main layers: the epidermis and dermis. The epidermis consists of the basal layer, spinous layer, granular layer, clear layer, and horny layer. Each layer has different types of cells and differs in function. The basal layer consists of a single column of cells that are attached to the basement membrane.

Typical basal keratinocytes have an oval nucleus, prominent nucleolus or nucleoli, and little heterochromatin. The basal keratinocytes contain melanosomes; various metabolic and synthesizing organelles such as mitochondria, lysosomes, rough endoplasmic reticula, and Golgi complexes; and cytoskeletal structures such as keratin intermediate filaments, microfilaments, and microtubules. Structures that help form the attachment and help to shape the basal layer are also present; these cells are known as desmosomes and hemidesmosomes.[4,5]

The spinous layer of the epidermis comprises two to four layers. The cells become progressively differentiated as they move outward toward the skin surface. The spinous layer cells first appear polyhedral and then become 667

668 more flattened as they develop and move outward. The spinous cells contain cellular organelles and keratin filaments. The cells of the uppermost one to two layers of the granular layer contain small, oval, membrane-bound organelles (300 nm) with alternating lamellae called lamellar granules (membrane-coating granules, keratinosomes, Odland bodies) formed in the Golgi region. They contain polar lipids such as phospholipids, glycosphingolipids, free sterols, and so-called probarrier lipids and hydrolytic enzymes that convert the probarrier lipids into stacks of neutral lipid-rich lamellae that assemble in the intercellular space, coat the surfaces of the cornified cells, and provide a barrier to the permeation of the skin. The spinous cells have abundant desmosomes that consist of adhesion plaques and submembranous plaques involved in cell cohesion.[4,5]

The granular layer consists of highly differentiated cells that are flattened polyhedrons with keratohyalin granules. In this layer of the skin, dephosphorylation and proteinolysis activate filaggrin, which cross-links and bundles with keratin filaments into large macrofilaments. Filaggrin is broken down in the stratum corneum to free amino acids important for the proper hydration of the epidermis. Lamellar granules present in the granular layer aggregate beneath the plasma membrane and fuse with it, opening a channel for the release of granule contents such as polysaccharides, glycoproteins, acid hydrolases, acid lipase, and probarrier lipids into the intercellular spaces. After release, polar lipids are remodeled into hydrophobic, neutral, lipid-rich lamellae that form an effective barrier. A dense layer of highly cross-linked proteins is deposited inside the inner leaflet of the membrane. Together with the membrane, this boundary is referred to as the cornified cell envelope, a rigid structure that resists degradations and is rich is glutamyl-lysine isopeptide cross-links. At the uppermost aspect of this layer, substances such as keratins, filaggrin, and the cornified cell envelope are passed on to the cornified cell layer.[4,5]

The cornified layer contains the largest and most numerous cells of any zone in the epidermis. Cells are large, flattened, and polyhedral; overlap with the margins; and associate through interlocking ridges and modified desmosomes. The contents of the cell are limited primarily to disulfide-bonded keratin filaments, highly cross-linked bundles of macrofilaments, and filaggrin. The compact organization of the proteins becomes looser toward the outer epidermal surface. The breakdown of filaggrin to its constituent amino acids in the outer cell layers accounts for the greater water-holding capacity of the cells and the more diffuse organization of the filaments. Uricanic acid is degraded from filaggrin with histidase and absorbs ultraviolet light. Therefore uricanic acid is important in ultraviolet light protection. The pyrrolidone carboxylic acid derived from glutamine is hygroscopic and helps to keep the skin hydrated even in a dry environment. The preserved trilaminar plasma membrane outside the cornified cell envelope becomes discontinuous and desquamates toward the upper portion of the cornified layer, so that the envelope serves as the real cell membrane.[4,5]

The dermis contains a variety of cells that are essential for the skin to function normally. The dermis contains cellular elements such as fibroblasts, macrophages, histiocytes, eosinophils, and mast cells in the fibrous matrix and nonfibrous matrix. The fibrous matrix consists of collagen and elastic fibers. The nonfibrous matrix consists of glycosaminoglycans and proteoglycans. The blood vessels, nerves, lymphatics, hair, and sebaceous and

apocrine glands are found within the dermis. The sebaceous and apocrine glands in the horse are larger and more numerous compared with those in other large animals species.[4,5]

The area that separates the epidermis from the dermis is known as the basement membrane zone. This layer of the skin functions as a scaffold for organization (important for growth and differentiation of keratinocytes) and repair (speeds up reepithelization), acts to regulate selective permeability by only allowing passage of molecules of the correct charge and molecular size, provides a physical intercellular barrier (tumor containment), and links epithelia to their underlying matrices. The basement membrane consists of structures such as tonofilaments, hemidesmosomes, laminin, fibronectin, proteins such as collagen, laminin-like molecules such as entactin and nidogen, anionic glycosaminoglycans such as heparin sulfate, anchoring fibrils, oxytalan filaments, elaunin fibers, microthread-like filamentous threadwork, and large glycoproteins such as fibrillin.[5]

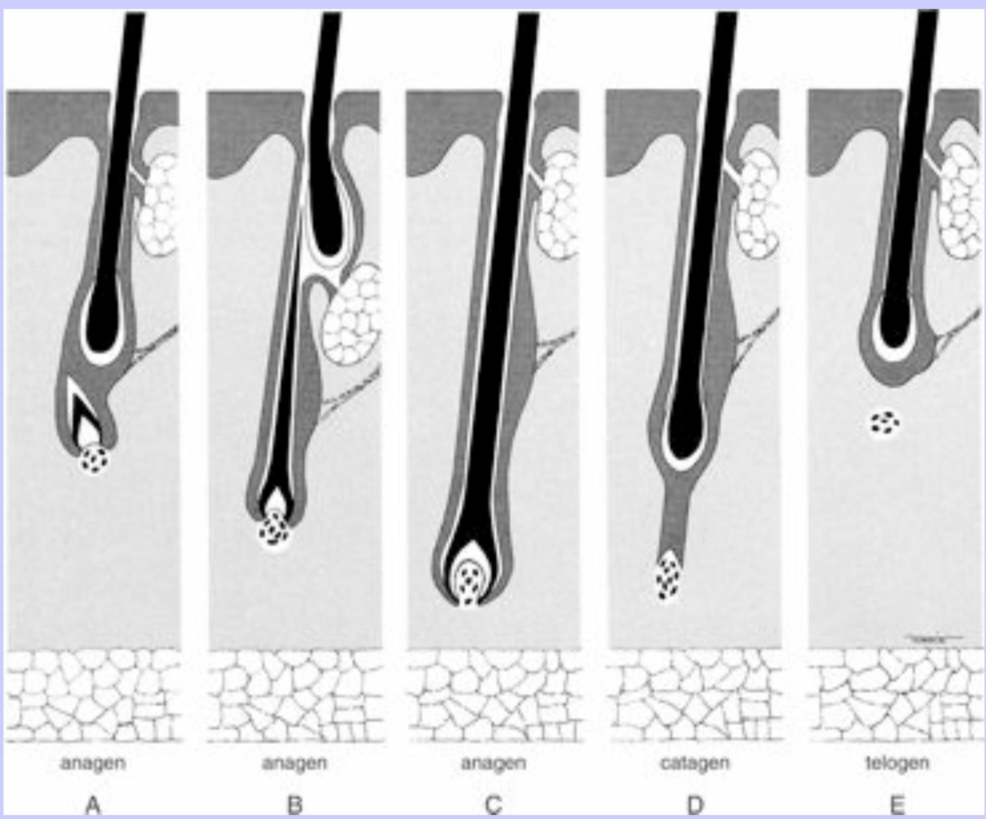
11.2.2 HAIR

The hair tends to cycle in a specific manner. Initially, hairs are in the growing or anagen phase, progressing through an intermediate or catagen phase into a resting or telogen phase (Figure 11-1). The period of time that hairs are in the catagen phase is short, and finding hairs in this stage of the cycle is difficult using a trichogram (plucking hairs and looking at them under the microscope). A variety of conditions including temperature, photoperiod, and hormones can affect the hair cycle.[1,6]

The hair follicles are located within the dermis and are associated with sebaceous and apocrine glands. Hairs are important in thermoregulation, protection of the skin from external factors, and as an ornament to attract other animals. The types of hairs found in equine skin are simple primary hairs. Horse hairs tend not to shed at once. Instead their hair sheds in patches or in a mosaic pattern.[1]

Ambient temperature affects the texture of the hairs. In warm temperatures the hair coat comprises thick, medullated hairs. Piloerection of hairs occurs to aid in cooling the body. In contrast, in cold temperatures the 668
coat comprises longer, finer, and poorly medullated fibers. This type of hair coat provides more insulation from 669
cold. The hairs of the fetlock, mane, and tail do not shed like the other hairs on the horse.[1]

Figure 11-1 Phases in the life cycle of a hair. **A,** Anagen begins with the renewal of the intimate relationship between the papilla and the undifferentiated cells that partially enclose it. **B,** As anagen proceeds, matrix cells generate a new hair that pushes upward toward the surface and in the process dislodges the old club hair. **C**, Mature anagen hair follicle consists of infundibular, isthmus, and inferior segments. **D,** During catagen, the entire inferior segment of the follicle shrivels upward as a thin cord of epithelial cells and is followed upward by the papilla. **E,** During telogen, the club hair rests in its cornified sac at the level of the hair erector muscle. (From Moschella SL, Herley HJ: *Dermatology*, ed 3, Philadelphia, 1992, WB Saunders.)



11.2.3 ADDITIONAL SKIN-RELATED STRUCTURES

The horse and other Equidae have skin structures unique to these species, including the ergot, chestnut, and hoof. The ergot is a small mass of cornified tissue located in a tuft of hair on the flexor surface of the fetlock. The

ergot is a vestige of the second and fourth digits of extinct Equidae. The chestnut refers to a mass of horny tissue on the medial surface of the radius and is believed to be a vestige of the first digit. The hoof is the horny covering over the distal end of the third digit. The hoof includes the frog, important for shock absorption and stimulation of blood flow to the foot, and other components that provide a firm structure to facilitate motion.

11.3 History

A patient history of the horse can provide the clinician with useful clues to help determine the underlying cause of a dermatologic problem. Figure 11-2 is an example of a form with different types of dermatologic questions. For example, most allergies manifest with the clinical sign of pruritus. The owner may notice the horse rubbing, scratching, licking, or chewing, or physical examination may reveal evidence of pruritus (i.e., broken hairs and 669
excoriations). Pruritus does not confirm a diagnosis of allergic disease. Other conditions such as parasitic 671
infestation or secondary bacterial or fungal skin infection may be pruritic. One may rule out these differential diagnoses by performing the diagnostic tests discussed later in this chapter.

Figure 11-2 Sample equine history form.

EQUINE DERMATOLOGY HISTORY FORM

Date ______

Age when purchased ______

What is this horse's use? ______

What is your complaint about the horse's skin? ______

Age of horse? ______ Age when skin problem started? ______

Where on the body did the problem start? ______

What did the skin problem look like initially? ______

How has it spread or changed? ______

Is the problem continual or intermittent? ______

What season did the problem start? ______

Is the problem seasonal or year-round? ______

If seasonal, what seasons is the disease present? ______

Does the horse itch? ______ If so, where? ______

Do any horses in contact with the affected horse have skin problems? ______

If so, are they similar or different from this horse's problem? ______

Do any people in contact with the horse have skin problems? ______

Do you use insect control? ______ If so, describe. ______

Do any relatives of this horse have skin problems? ______ If yes, explain. ______

Please list any injectable, oral, or topical medications that have been used to treat the problem (veterinary or "home remedies"): ______

Did any help the condition? ______ If yes, which ones? ______

Did any aggravate the condition? ______ If yes, which ones? ______

Describe the environment where the horse is kept: Indoors ______

______ Outdoors ______

What is the horse fed? ______

What feed additives do you use? ______

What is your deworming schedule? ______

Did the horse receive ivermectin? ______ If so, when? ______

List any other major medical problems or drugs that the horse received: ______

List any additional information you feel is relevant to the skin disease: ______

Insect allergies and atopy frequently recur seasonally. However, some horses may have year-round or nonseasonal pruritus with insect allergies or atopy, which is more common in warm climates in the United States. One also should include food allergy on the list of differential diagnoses for horses with nonseasonal pruritus.

Questions as to whether other horses in the stabling or pasture facility have dermatologic lesions may be important. Knowing if grooming aids (brushes, combs, etc.) are used on more than one horse is important. Pruritus that affects multiple animals may indicate the possibility of a parasitic or infectious process.

Response to previous therapy is another useful historical clue. One should determine the dose and frequency of medication administration. If the appropriate drug or drug dose is not used, then the patient may not respond.

Other factors to consider include feed, stabling environment, and supplements or other medications (wormers, sprays, shampoos, etc.) used regularly. If any of this changed before the development of the dermatologic lesions, the change may be related to the problem in the horse.

11.4 Physical Examination

One should consider the type of skin lesions and lesion distribution when performing a physical examination on the equine patient with dermatologic disease. Pustules and vesicles are fragile skin lesions that are not found easily and are most common in bacterial or autoimmune skin diseases. Pustules and vesicles are considered primary lesions. Other examples of primary lesions include papules, wheals, erythema, and nodules. Secondary lesions commonly observed in horses may include scale, crusts, excoriations, fistulae, ulcers, necrosis, hyperpigmentation, hypopigmentation, lichenification, hyperhidrosis, and scars.

The location of lesions is important because certain dermatologic conditions tend to occur on certain areas of the body. This tendency is especially true with parasitic hypersensitivity reactions because certain parasites have a predilection for certain areas of the body.[7] For example, pinworms tend to cause intense pruritus of the tailhead, and black flies tend to have a predilection for the head, ears, and ventral abdomen. More detailed information concerning insect feeding preferences is covered in the insect hypersensitivity section. One should examine the horse for evidence of external parasites such as ticks or flies.

The clinician always should perform a thorough physical examination, including determining the temperature, heart rate, and respiratory rate. If abnormalities in any of these parameters exist, the horse may have a systemic disease or more than one medical problem. For the health of the animal, exploring and treating all possible medical problems is important.

11.5 Common Causes of Pruritic Dermatoses

Pruritus is the sensation to rub, lick, scratch, or chew.[8] Horses most commonly rub the skin and hair coat when they are pruritic (Figure 11-3). Clinical evidence that a horse is pruritic may include the presence of broken hairs, excoriations, hemorrhagic crust, alopecia, lichenification (thickening of the skin), and hyperpigmentation. Lichenification and hyperpigmentation occur most commonly following chronic inflammation and pruritus.

Conditions that tend to be pruritic include parasite infestations such as lice, mites, ticks, *Onchocerca, Habronema,* and pinworms or allergic reactions such as insect hypersensitivity, food allergy, contact allergy, and atopy. Occasionally, pruritus occurs with bacterial or fungal infections.

11.5.1 PARASITIC SKIN DISEASES

11.5.1.1 Lice (Pediculosis)

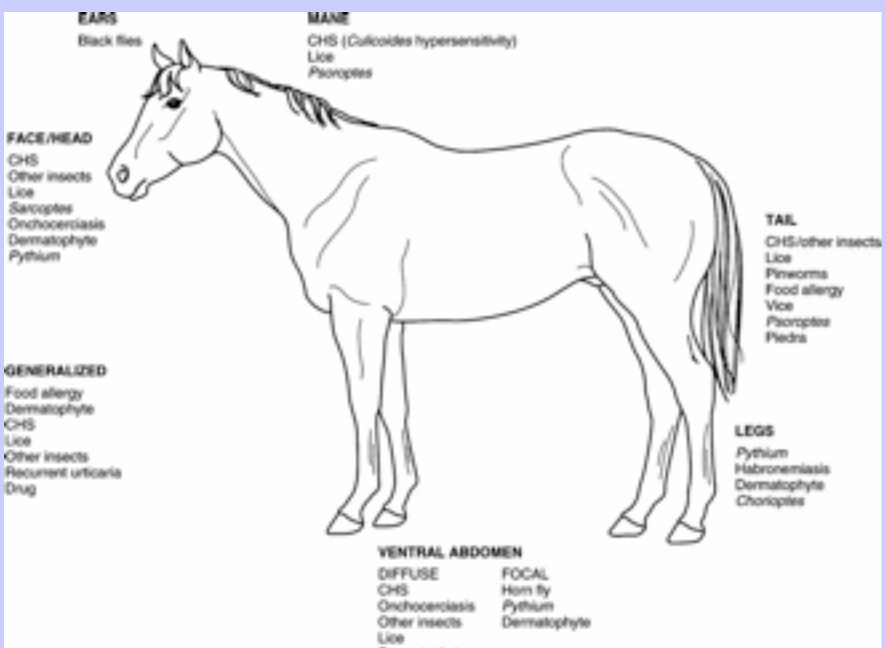
Two types of lice may be found on horses. Biting lice feed on epidermal debris, whereas sucking lice feed on blood and lymph. *Haematopinus asini,* the sucking louse of horses, most commonly infests the mane and tail and the hairs behind the fetlock and pastern. The biting louse, *Damalinia equi,* tends to feed on the dorsolateral trunk.

Lice are host-specific and complete their entire life cycle on the host. Female lice attach their eggs to hairs. In cool moist environments, lice can live for 2 to 3 weeks; they only live a few days off of the host. Lice infestations are transmitted by direct or indirect contact. Brushes, combs, and tack serve as fomites for transmission of lice. Adult horses may act as asymptomatic reservoirs for infection.

Lice infestations may occur year-round, but they are more common in the winter in northern climates. Cooler skin and hair coat temperatures are more favorable for development of eggs within the female, oviposition, and egg development.[9] Skin temperatures on the legs of horses, with the possible exception of Draft Horses, are too cold for louse development.

Louse infestation has no age, breed, or sex predilection in horses. Affected horses tend to be restless and have a poor appetite. They have a dry, dull hair coat with patchy areas of hair loss and excoriation. The coat may 671
appear moist and have a sour or mousy odor. Skin fasciculation may be the only evidence of early infestations 672
in foals. Some horses may be asymptomatic carriers that are identified only when foals or other susceptible animals become infested. Heavy infestations of sucking lice may cause anemia or severe debilitation.

Figure 11-3 Regional pruritus: differential diagnosis of pruritic skin diseases.



Diagnosis of lice infestations is by demonstration of adults and/or eggs on the hairs. Sometimes one cannot visualize lice easily in direct light. In these circumstances, the veterinarian may need to comb the hair coat with a fine-toothed comb to find the lice. Skin biopsies may reveal a nonspecific superficial perivascular eosinophilic dermatitis with or without intraepidermal microabscesses.[10]

When dealing with a lice infestation, the veterinarian should treat all animals on the premises. Ivermectin at 200 μg/kg orally every 2 weeks for three treatments is effective for treating sucking lice. Biting lice do not respond to ivermectin treatment, and so one should treat affected horses with other medications, such as dips. Common types of dip that one may use to treat sucking and biting lice infestations include lime sulfur, pyrethrins, methoxychlor, malathion, coumaphos, crotoxyphos, pyrethroids, and lindane. Lime sulfur and pyrethrin dips have fewer associated adverse reactions in horses than do other dip treatments. One should take care to use any product according to label directions. None of these treatments affect lice eggs, and two to three repeat applications of the dip are recommended at 2-week intervals. For optimal efficacy, one should treat the whole body of the horse when applying the dips. Other precautions include cleaning and disinfecting all tack and grooming supplies (brushes and combs); decontaminating the stabling area using a commercial premise spray used to kill fleas, because lice may survive for days to weeks in the environment; and although reinfestation is difficult to prevent, treating animals returning from shows, breeding farms, or training facilities prophylactically. 672

673

11.5.1.2 Mites (Mange)

A variety of mites may infest horses. *Sarcoptes scabiei* var. *equi* (scabies, head mange), *Chorioptes equi* (leg mange), *Psoroptes equi* (body mange), *Pyemotes tritici* (straw itch mite), and *Trombicula* and *Eutrombicula* species (chiggers) are species associated with equine pruritic skin disease.[7] The pruritus accompanying a mite infestation results from a combination of mechanical irritation and hypersensitivity to the mite and by-products of the mite (i.e., feces).[11,12] The primary skin lesion from a mite infestation is a maculopapular eruption. These skin lesions are often difficult to find with chronic infestations.

11.5.1.2.1 Sarcoptes scabiei

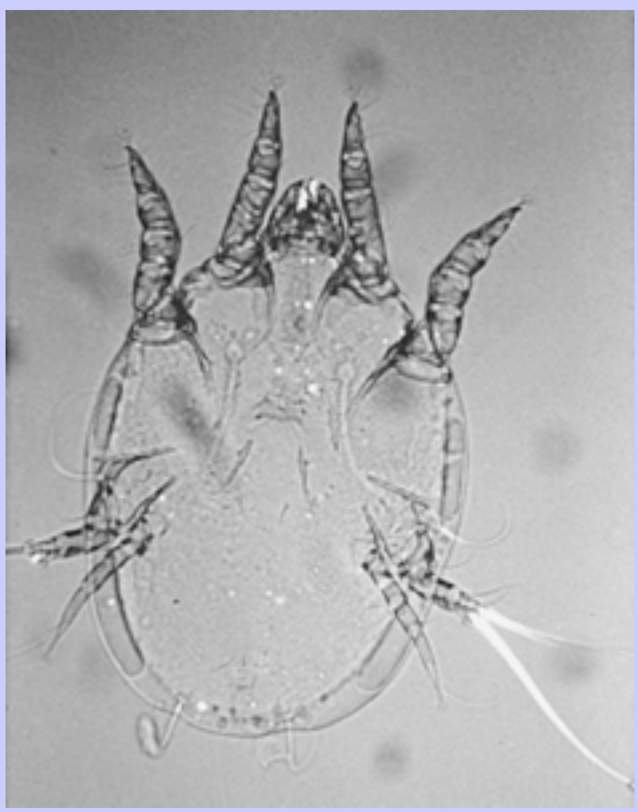
In the United States, *Sarcoptes scabiei* infestations in horses are a reportable disease.[7] This mite is highly contagious and infests horses and transiently infests human beings (self-limiting disease) in contact with parasitized horses. This parasite is capable of surviving off the host for up to 3 weeks, and transmission of scabies by fomites or in the environment is possible. Scabies mites burrow in the superficial epidermis and lay their eggs. In early infestations, mites are found in highest concentration around the head and neck. These mites seem to prefer the ears on horses. As disease progresses, mites usually spread over the entire body. A scabies infestation in a horse results in intense pruritus and generalized scaling and crusting with excoriations and lichenification. A secondary skin infection may result from the pruritus. One may elicit the itch-scratch reflex by scratching the horse over the withers, causing the horse to tuck its nose close to its chest and make smacking noises and exaggerated lip movements. This reflex suggests scabies but is not diagnostic, and one may elicit the reflex in some normal horses.[13] The scabies mite is circular with short legs, a terminal anus, and long unjointed pedicles. Unfortunately, as in other species, the scabies mites are difficult to find on skin scrapings. Therefore a negative skin scraping does not assure that the horse does not have scabies.

Ivermectin at a dose of 200 μg/kg orally is effective for treating horses with scabies. As in other species, one should repeat ivermectin treatment at 2-week intervals for a total of two to three treatments. Within 2 weeks the eggs hatch and new adult mites are present. Topical treatments such as lime sulfur dip, lindane, coumaphos, diazinon, malathion, or toxaphene also have been used. One should dip horses every 7 to 10 days for three to six treatments, treat all horses in contact with the infested horse, and decontaminate fomites (tack, brushes, etc.) and the environment.

11.5.1.2.2 Chorioptes equi

Chorioptes equi mites are host-specific and do not parasitize human beings (Figure 11-4). Unlike the scabies mite, infestation with *C. equi* is not a reportable condition. *C. equi* mites spend their entire life cycle on the host feeding on epidermal debris. Preferred feeding sites include the distal limbs and perineum. Infested horses exhibit intense pruritus with stomping of feet and rubbing of the perineal area. Skin lesions include alopecia, erythema, and crusting of the pasterns, fetlocks, or perineum. Draft Horses or other horses with feathered fetlocks are predisposed to *C. equi*. The mite tends to be more common in the winter months. One should include *C. equi* in the list of differential diagnoses for horses with pastern dermatitis or greasy heel. Treatment of this mite is the same as for *S. scabiei*. However, ivermectin-resistant *C. equi* mites have been reported, and topical dip therapy may be indicated if the horse does not respond to oral therapy. If one uses a topical medication, clipping the hair around the fetlocks and pasterns to ensure optimal contact of the dip with the skin and mites is advisable.

Figure 11-4 *Chorioptes* mite.



11.5.1.2.3
Psoroptes equi

Psoroptes equi mite infestations are a reportable condition in horses in the United States. *P. equi* mites are highly contagious to other horses but do not infest human beings. These mites do not burrow but live on the skin surface. They are biting mites that feed on serum and cellular components. Transmission of *P. equi* mites is by direct contact and exposure to fomites. Mite infestations tend to begin on the forelock, mane, and tail and spread to the trunk. These mites have been known to infest the ear canal and cause otitis 673
externa. Affected horses typically show head shaking or rubbing. As with many other mites, pruritus results 674
in alopecia, crusts, excoriations, and ulcers on the skin. The intensity of pruritus varies. History and clinical signs suggest the diagnosis of *P. equi* mange. One requires skin scrapings to diagnose this condition definitively. *P. equi* has an oval body with segmented pedicles. Treatment of *P. equi* is similar to that described for sarcoptic mange.

11.5.1.2.4
Trombiculidiasis

Trombiculidiasis (red bugs, harvest mites) is caused by an infestation with larvae of free-living adult mites (genus *Eutrombicula* or *Trombicula*). Larvae are most prevalent in grasses, forests, or swamps in late summer and fall. Small rodents are the natural host. Pathognomonic skin lesions are papules or wheals with a small orange, red, or yellow dot (trombiculid larvae) in the center. Areas of the body most commonly infested are the face, muzzle, distal limbs, ventral thorax, and abdomen. Diagnosis is by observation of the distinctive lesion with the larvae in the center. Trombiculidiasis is a self-limiting disease. However, some horses are uncomfortable with this infestation and should be treated. Recommended treatments include lime sulfur dip and pyrethrin sprays or dips as a one time treatment in association with prednisolone or prednisone at a dose of 0.5 mg/kg orally for 3 to 5 days.

11.5.1.2.5
Pyemotes tritici

Pyemotes tritici (straw itch mite) normally parasitizes the larvae of grain insects. Occasionally this mite parasitizes human beings and horses.[14] Infestation in horses occurs from contaminated hay fed in overhead racks. The mite produces a maculopapular crusted eruption on the head, neck, and trunk that is only occasionally pruritic. Diagnosis is based on history and clinical examination. This disease is self-limiting, and one should remove contaminated forage or feed the horse from the ground until all contaminated forage has been consumed. Infestations from fomites or hay fed on the ground have not been reported.

11.5.1.2.6
General Comments About Mites

Regardless of the type of mite present on the horse, skin scrapings should be part of the diagnostic workup. With the exception of lice and trombiculid larvae that one can see with the naked eye, one can diagnose mite infestations best by microscopic examination of skin scraping samples.

11.5.1.3
Ticks

Ticks are an important ectoparasite in the horse because of their potential role in disease transmission, including a variety of viral, protozoal, rickettsial, and bacterial infections. Tick infestations are most common in the spring and summer.

Argasid ticks lay eggs in cracks and crevices in the environment, and immature ticks infect hosts after hatching. Larvae and nymphs suck blood and lymph and then drop off to develop into adults. These ticks infest barns, sheds, and other areas where animals are found. In horses, *Otobius megnini* (spinose ear tick) tends to infest the ears and ear canal. Clinical signs of infestation include otitis externa, head tilt, head shaking, ear rubbing and occasionally aural hematomas.

Dermacentor, Ixodes, and *Amblyomma* species are the most common ixodid ticks of horses. These ticks are found outdoors and have complicated life cycles, and all stages of the life cycle are parasitic. The severity of clinical signs depends on the density of the infestation and whether the horse develops a hypersensitivity reaction to the bites. Infestations occur most commonly on the ears, face, neck, groin, distal limbs, and tail. Early lesions consist of papular to pustular eruptions that rapidly develop into crusts, erosions, ulcers, and hair loss. Hypersensitivity reactions may be local or general. Local responses appear as nodules that develop at the site of the tick bite. Although the pathogenesis is unknown, cutaneous basophil hypersensitivity is believed to be involved.[15] Systemic reactions are characterized by whole-body urticaria or multifocal urticarial plaques. In Australia, a hypersensitivity reaction to *Boophilus microplus* has been observed in sensitized horses.[16] Intense pruritus, papules, and wheals develop as soon as 30 minutes after ticks begin to feed.

Definitive diagnosis is by observation of ticks attached to the horse or in the ear canal. Treatment aims at killing ticks on the horse. One should apply pyrethrin or pyrethroid sponge-on dips to the body of the horse, taking extra care to soak skinfold areas. Usually only one treatment is necessary unless reinfestation occurs. Resistance to insecticides can occur rapidly, and knowledge of local resistance patterns is important. Infestations of *O. megnini* require mechanical removal of as many ticks as possible. One part rotenone and three parts mineral oil applied twice weekly is an effective otic parasiticide for horses. The author has used a commercially available pyrethrin otic preparation (Otomite Plus, Vibac, Fort Worth, Texas) for small animals in horse ears with success. Ivermectin also has been shown to be effective in treating ticks at a dose of 200 µg/kg orally.

11.5.1.3.1 Onchocerciasis

Onchocerciasis is a nonseasonal skin disease of the horse caused by the parasite *Onchocerca cervicalis*. This nematode lives in the ligamentum nuchae and produces microfilariae that migrate to the skin and are ingested by the intermediate host, *Culicoides* species. Microfilarial populations in the skin vary, and the highest concentrations occur in the dermis of the face, neck, and ventral midline, especially the umbilicus (Figure 11-5).[17] Microfilarial populations vary seasonally and are highest in the spring, which interestingly is the peak season for the *Culicoides* vector.[18] Microfilariae are more superficial in the dermis during the spring and summer months. Clinical signs of onchocerciasis are believed to be caused by an idiosyncratic 674
hypersensitivity reaction to microfilarial antigen(s) because many horses that have circulating microfilariae 675
do not have any gross skin or ocular lesions.[19] Whether the reaction is directed only at dying or dead microfilariae is unknown.

Figure 11-5 Ventral midline dermatitis caused by onchocerciasis.

Onchocerciasis has no breed or sex predilection and usually affects horses 4 years of age and older. Clinical signs are nonseasonal but may be worse in the spring and summer, most likely because of the added irritation from the vector. Lesions may occur on the face and neck, on the ventral chest and abdomen, or in all these areas.[20,21] Early lesions begin as a thinning hair coat. As the disease progresses, lesions may vary from focal to generalized areas of alopecia, scaling, crusting, and plaques. Affected areas may be excoriated severely, ulcerated, oozing, and lichenified. Annular lesions in the center of the forehead suggest the disease (Figure 11-6). Leukoderma usually develops at the site of lesions and is irreversible. Ocular lesions include sclerosing keratitis, vitiligo of the bulbar conjunctiva, white nodules in the pigmented conjunctiva, uveitis, and a crescent-shaped patch of depigmentation bordering the optic disk.[22]

One may make a presumptive diagnosis of onchocerciasis by demonstrating the microfilariae in the skin of animals with compatible historical and clinical findings. Skin scrapings and direct blood smears are often negative. One can demonstrate microfilariae most reliably with a mince preparation or via histologic examination of skin from a biopsy specimen.[21] Mince preparations require a 4- or 6-mm punch specimen of tissue obtained from the ventral abdomen. One places the tissue specimen in a Petri dish with a small amount of physiologic saline, minces it with a scalpel blade or razor, and incubates it at room temperature for 30 to 60 minutes. One then examines the specimen microscopically for evidence of the rapid motion of the microfilariae. Skin biopsies reveal a superficial perivascular eosinophilic dermatitis. Often microfilariae are visible in the superficial dermis.[7]

Figure 11-6 Equine onchocercosis.

Ivermectin at a dose of 200 μg/kg orally is the treatment of choice.[7,20,23] A single dose often produces remission of clinical signs within 2 to 3 weeks. However, some horses require two to three monthly treatments before clinical signs resolve. Approximately 25% of horses have an adverse reaction, such as ventral midline edema or pruritus, which occurs 1 to 10 days after treatment. In rare cases, severe umbilical and eyelid edema and fever may occur. In confirmed cases of onchocerciasis, one should perform a

thorough ocular examination to look for any signs of eye disease associated with onchocerciasis. Anecdotal reports suggest treatment may precipitate an episode of uveitis.

Prednisolone or prednisone at a dose of 0.5 mg/kg orally may be necessary in the first week of treatment to prevent exacerbation of skin and ocular lesions as a result of massive destruction of microfilariae but is not routinely recommended. Indications include the development of ventral midline edema, pruritus, and fever. None of the currently available anthelmintics kill adult parasites in the ligamentaum nuchae, and affected individuals require periodic retreatment with ivermectin when clinical signs recur. The prevalence of cutaneous onchocerciasis has decreased significantly with the advent of routine dewormings with ivermectin. 675

676

11.5.1.3.2 Habronemiasis

Cutaneous habronemiasis is a common nodular skin disease caused by three species of nematodes: *Habronema muscae, H. majus (H. microstoma),* and *Draschia megastoma (H. megastoma)*. The house fly is an intermediate host for *H. muscae* and *D. megastoma,* whereas the stable fly is the intermediate host for *H. microstoma*. The normal life cycle for these parasites is similar. Adult nematodes live in the stomach and produce larvae. Larvae are passed in the feces and ingested by maggots of the foregoing intermediate hosts. The intermediate host deposits infective larvae near the mouth of the horse, which swallows them. Cutaneous habronemiasis occurs when intermediate hosts deposit infective larvae on skin, open wounds, or chronically wet areas.

A horse with cutaneous habronemiasis has ulcerative nodules in the spring and summer that partially or completely regress in the winter. No breed, sex, or age predilection exists. Some horses may be predisposed to cutaneous habronemiasis, exhibiting clinical signs each year, whereas other horses on the same premises never develop this condition.

Skin lesions of habronemiasis occur most commonly on the legs, urethral process of the penis, prepuce, medial canthus of the eye, or any area of trauma to the skin. Other areas that may be infected include the conjunctival sac, the lacrimal duct, and the third eyelid. Single or multiple nodules may be present. In most cases, pruritus is present, presumably following a hypersensitivity reaction to the parasite. The intensity of pruritus may vary from mild to severe. In severe cases in which ocular lesions are present, the horse can suffer from photophobia, epiphora, and chemosis. Dysuria can occur when lesions affect the urtheral process.

Lesions often are ulcerated and appear similar to exuberant granulation tissue. Yellow granules approximately 1 mm in diameter may be present.[24,25] Microscopic examination of these granules does not reveal branching hyphae such as one frequently observes with granules from pythiosis or zygomycosis lesions.

Differential diagnoses for cutaneous habronemiasis include bacterial granuloma, fungal granuloma, pythiosis, exuberant granulation tissue, squamous cell carcinoma, and equine sarcoid. Habronema may be present concurrently with other dermatologic conditions, and biopsy is important for a complete and definitive diagnosis.

Diagnosis is based on history, physical examination, cytologic examination, and biopsy of lesions. Cytologic examination of exudate sometimes reveals the presence of nematode larvae. These larvae are large (3 mm by 60 μm), with a spiny tail, and usually are motile. Skin biopsies reveal a nodular to diffuse

granulomatous dermatitis with large numbers of mast cells and eosinophils. Foci of coagulation necrosis are characteristic.[26,27] Sometimes this area of necrosis contains cross sections of larvae.

Treatment of cutaneous habronemiasis should include control of the associated hypersensitivity reaction and elimination of the parasite. Treating horses with ivermectin alone is not always effective. The author and co-workers examined 14 horses between 1988 and 1998 that had been treated with ivermectin in the preceding month and had intralesional habronema larvae present on biopsy. Similarly, 5 of 31 horses treated with ivermectin for habronemiasis required an additional treatment 2 to 4 weeks later.[28] One may treat the hypersensitivity reaction with systemic corticosteroids such as prednisone or prednisolone at a dosage of 1 mg/kg once daily for 10 to 14 days with a gradual decrease over an additional 2-week period. Corticosteroids and dimethyl sulfoxide (DMSO) often are combined with fenthion, thiabendazole, ronnel, or trichlorfon in a variety of topical preparations for treatment of habronemiasis.[27] Some more common topical lesional medications include (1) 1 oz dexamethasone (2 mg/ml) in 1 oz 90% DMSO, and 1 oz 20% fenthion; (2) 3 oz 90% DMSO in 15 ml dexamethasone (2 mg/ml), 40 ml nitrofurazone solution, and 1 oz trichlorfon powder; and (3) 30 ml 20% fenthion, ¾ lb petrolatum (heated), 10 mg triamcinolone acetonide powder, and 90 ml 90% DMSO. Ivermectin sometimes is used concurrently with these topical medications.

One may treat conjunctival habronemiasis with topical echothiophate drops 3 times a day to kill larvae in combination with an ophthalmic ointment that contains dexamethasone and an antibiotic.

Fly control is an essential part of treatment. Oil-based fly sprays tend to last longer than water-based fly sprays. Products that contain permethrin are effective.

Prognosis for horses with habronemiasis is good with appropriate and timely treatment. The veterinarian should warn the owner that habronemiasis may recur in subsequent years. Fly control is essential to preventing recurrence.

11.5.1.3.3 Pinworms

Equine pinworms, *Oxyuris equi,* cause intense anal pruritus. Adult pinworms are found in the colon. The female worm migrates down the gastrointestinal tract and deposits eggs around the anus. These eggs are cemented to the skin with a thick, sticky, yellow-gray substance. Horses develop perianal pruritus as a result of this sticky substance, which contains the eggs. In severe infestations horses may develop vague abdominal discomfort. This abdominal discomfort results directly from inflammation of the cecal and colonic mucosa in response to third- and fourth-stage pinworm larvae.[29]

Eggs develop to the infective stage within a 4- to 5-day period. At this time the cement substance cracks and dries and then detaches from the skin as flakes. These flakes contain a large number of eggs that adhere to walls, buckets, and other objects in the environment. 676

677

Because one often does not observe ova of *O. equi* on routine fecal flotation, a diagnosis of pinworms is based on clinical signs and identification of pinworm eggs on cellophane tape preparations. One presses a piece of clear adhesive tape to the skin around the anus and removes the tape and places it on a slide for microscopic examination for oval ova with an operculum or plug at one end.

O. equi is treated easily with a variety of anthelmintic agents. Anecdotal reports exist of occasional resistance to ivermectin and pyrantel; these horses respond to treatment with fenbendazole. One may treat the horse once with fenbendazole and remove it from the environment for 1 month. (Pinworms can survive

in the environment under ideal conditions for up to 1 month.) Alternatively, one may treat horses with fenbendazole 3 times at 2- to 3-week intervals.

11.6 Allergies

11.6.1 INSECT HYPERSENSITIVITY

Insect hypersensitivity is a common cause of skin disease in the horse. Mosquitoes and species of *Culicoides* (biting midges, "sweet itch"), *Simulium* (black flies), *Tabanus* (horse flies), *Chrysops* (deer flies), *Stomoxys calcitrans* (stable flies), *Haematobia* (horn flies), *Musca* (house flies), bees, and wasps cause skin lesions in horses.[7]

Insect hypersensitivity reactions are seasonal in colder climates, can be nonseasonal in warmer climates, and may affect any age, sex, or breed of horse. This dermatologic condition may have an inherited component, but specifics of these claims have not been verified. The distribution of skin lesions varies and may depend on the type of insect involved. Certain insects have preferred feeding sites.[7,30] The black fly tends to feed on the head, ears, and ventral abdomen. Stable flies prefer feeding on the lower legs but also have been known to feed on the ventral abdomen, chest, and back. The location for *Culicoides* spp. feeding is species dependent. Classically, *Culicoides* spp. feed on the dorsal surface of the horse (especially the mane and tail areas), face, and ears (Figure 11-7). In Florida, some *Culicoides* spp. prefer feeding on the lower legs, ventral trunk and neck. Horn flies feed on the ventrum around the umbilicus (Figure 11-8). Mosquitoes prefer feeding on the lateral aspects of the body.

A few insects bite anywhere on the body and do not prefer a specific location. Examples include deer flies, horse flies, house flies, bees, and wasps.

Some insects require a specific environment to propagate. Knowledge of these requirements may be helpful in establishing insect control programs. *Culicoides* spp. and mosquitoes prefer free-standing stagnant water for propagation. In contrast, black flies prefer moving water such as a stream, brook, or river. Horn flies are obligate parasites of cattle that require fresh cattle feces for reproduction. Several species of insects, including stable flies and house flies, prefer decaying vegetation or manure for reproduction. They tend to be a bigger problem when sanitation practices at the stabling facility are problematic.

Figure 11-7 Two-year-old horse with *Culicoides* hypersensitivity.

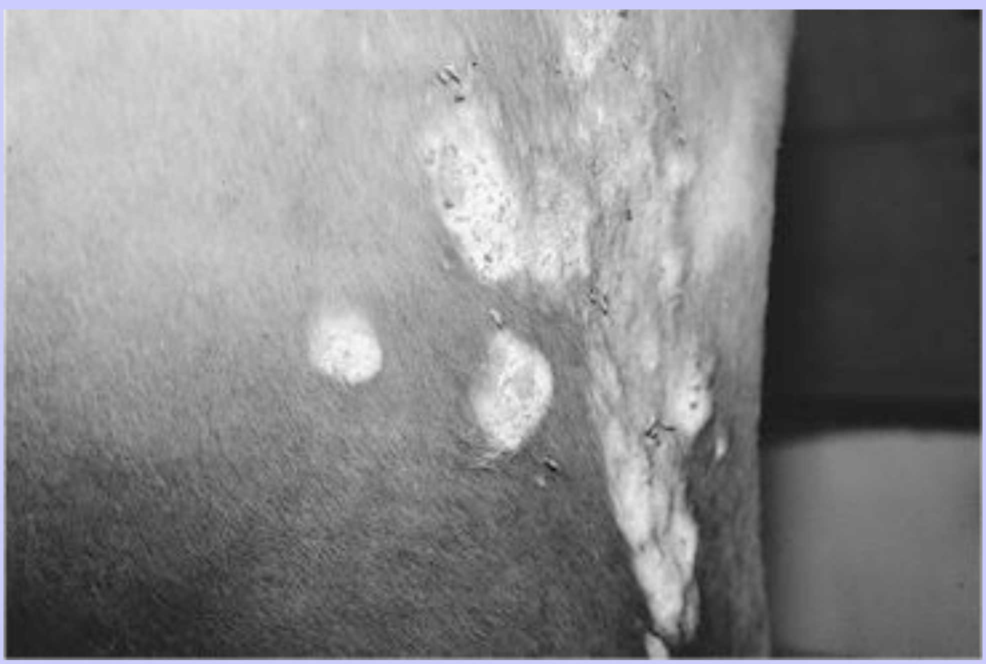
The time of day that an insect prefers to feed also differs between species. Horseflies, stable flies, black flies, and horn flies are usually active during the daylight hours. Mosquitoes and most *Culicoides* spp. are active at night. Mosquitoes are most active at dusk and the first 2 hours after sunset. If the time of feeding is known for the potential offending insect, the horse may be stalled during peak feeding hours to limit exposure.

Types of dermatologic lesions seen with equine insect hypersensitivity include pruritus, alopecia, excoriations, and lichenification. A generalized papular-crusted eruption also may occur.

Diagnosis of insect hypersensitivity is based on a compatible history, physical findings, and elimination of other causes of pruritus in the horse. Skin scrapings show no abnormalities. Skin biopsies may reveal the presence of a superficial or deep perivascular eosinophilic dermatitis with epidermal spongiosis (intercellular edema of the epidermis), necrosis, and collagen degeneration. Intradermal skin testing is useful for diagnosing insect hypersensitivity.[31] Some insect allergens are inconsistently available (e.g., *Culicoides* spp.), and purchase of insect allergens for the nonspecialist veterinarian may be cost-prohibitive. Fortunately, therapy and environmental control measures are similar for most biting and flying insects, and therefore confirming the diagnosis by intradermal skin testing may not be crucial.

677
678

Figure 11-8 Alopecia with some crusting around the umbilicus on a horse with horn fly infestation.



Treatment of insect hypersensitivity involves insect control and judicious use of glucocorticoids.[31] Boxes 11-1 and 11-2 and Table 11-1 summarize recommendations. Ideally, one should stable horses during the target peak feeding period for insects and should screen windows with a small-meshed screen and spray with a residual parasiticide. If possible, one should eliminate bedding areas for flies (e.g., standing water and manure). Spraying horses with residual insecticides (e.g., pyrethrins or pyrethroids) is useful, and sprays containing permethrin and pyrproxifen (Knock-Out Spray, Vibrac, Fort Worth, Texas) are effective for treating horses with *Culicoides* spp.

hypersensitivity. Anecdotal reports suggest that weekly application of fipronil (Frontline, Merial, Iselin, New Jersey) may be useful for treating horses with *Culicoides* spp. hypersensitivity. Avon Skin So Soft bath oil (Avon Products, Inc., New York, New York) mixed in equal volumes with water has been used to repel insects in horses. However, one should use this product with care because contact dermatitis has been reported. One should follow label recommendations with changes depending on the response of the individual horse. Cattle tags impregnated with insecticide may be helpful if attached to manes, tails, or halters.

Anecdotal reports suggest the importance of applying repellents and insecticide sprays to the horse when the skin is cool and dry. This may minimize development of sensitivity reactions to products by limiting percutaneous absorption. Many horses are sensitive to petroleum-based products and develop erythematous skin and hair loss in areas where the insecticide, fly wipe, or bath oil has been applied to the skin. If a horse has a history of this type of reaction, performing an open patch test with any new product before applying the spray over the entire body is advisable. One applies a small amount of the test substance to an area of skin and observes the site for 72 hours for signs of erythema, swelling, and hair loss. Fly masks or fly sheets are useful adjunct therapy for control of insects.

In many cases, insect control alone is insufficient to alleviate discomfort and clinical signs. Hydroxyzine hydrochloride may be beneficial in some horses with insect hypersensitivity when administered orally at a dose of 200 to 400 mg every 8 to 12 hours.[32] This drug also has been useful in managing insect-induced urticaria. Side effects associated with hydroxyzine in horses include sedation or hyperactivity. If the horse does not respond after hydroxyzine administration, one may try systemic corticosteroids. The recommended dose for prednisone or prednisolone is 1 mg/kg orally administered daily until the pruritus is relieved (usually 1 to 2 weeks); one then tapers the dose to the lowest effective every-other-day dose.

11.6.1.1

BOX 11-1 PRIMARY MANAGEMENT STRATEGIES FOR COMMON EQUINE PESTS

11.6.1.1.1

1. Stabling

Tabanids: Diurnal and crepuscular periods

Black flies: Diurnal and crepuscular periods

Biting midges: Under fans; nocturnal and crepuscular periods

11.6.1.1.2

2. Exclusion Devices

Black flies: Ear nets

House flies: Face masks

Face flies: Face masks

11.6.1.1.3

3. Hay and Manure Management

Stable flies: Particularly hay in pastures

House flies: General sanitation

11.6.1.1.4 4. Cattle Management

Horn flies: Control pest on natural host

Face flies: Undisturbed cattle manure requisite for larval development

11.6.1.1.5 5. Water Management

Mosquitoes: Only certain species

Biting midges: Only certain species

11.6.1.1.6 6. Source Identification and Removal

Straw itch: Normally infested hay

Blister beetle: Normally products containing alfalfa

11.6.1.1.7 7. Restricted Grazing or Movement

Chiggers: Erratic distribution in spring or fall

Ticks: Mowing and understory control also helpful

Tabanids: Allow horses to escape from wooded areas

Poultry pests (sticktight fleas and lice): Separate horses from poultry

Modified from Foil L, Foil C: Control of ectoparasites. In Robinson NE, editor: *Current therapy in equine medicine,* ed 3, Philadelphia, 1992, WB Saunders.

Anecdotal reports suggest that a DMSO dervivative, methylsulfonyl methane, may be effective as an aid to relieve pruritus associated with equine insect hypersensitivity. This medication is available as a powder to be sprinkled on food and should be used according to label directions.

Fatty acids have been recommended for control of pruritus associated with insect hypersensitivity.[33,34] The effectiveness of this therapy may depend on dose and fatty acid source. One study in Florida used flaxseed oil in

horses with *Culicoides* spp. hypersensitivity and found no benefit in decreasing pruritus.[33] A study in Canada demonstrated that flaxseed meal was beneficial in treating pruritus in horses with *Culicoides* spp. hypersensitivity.[34] These apparently disparate results may be explained by geographic factors or the source of flaxseed.

TABLE 11-1 Pesticides Recommended for External Parasite Control on Horses[*]

RESIDUAL INSECTICIDES	OTHER COMPOUNDS
PYRETHROIDS	**REPELLENTS**
Cypermethrin	MGK 326 *di-n-propyl isocinchomeronate*
Fenvalerate	Stabilene: butoxypolypropylene glycol
Permethrin	
Resmethrin	
Tetramethrin	
S-Bioallethrin	
Sumethrin	
ORGANOPHOSPHATES	**BOTANICALS**
Coumaphos	Pyrethrins (also insecticidal)

* Categories may overlap; for example, some pyrethrins are also insecticidal, and some pyrethroids are repellent. William B. Warner and Roger O. Drummond assisted in compiling this list.

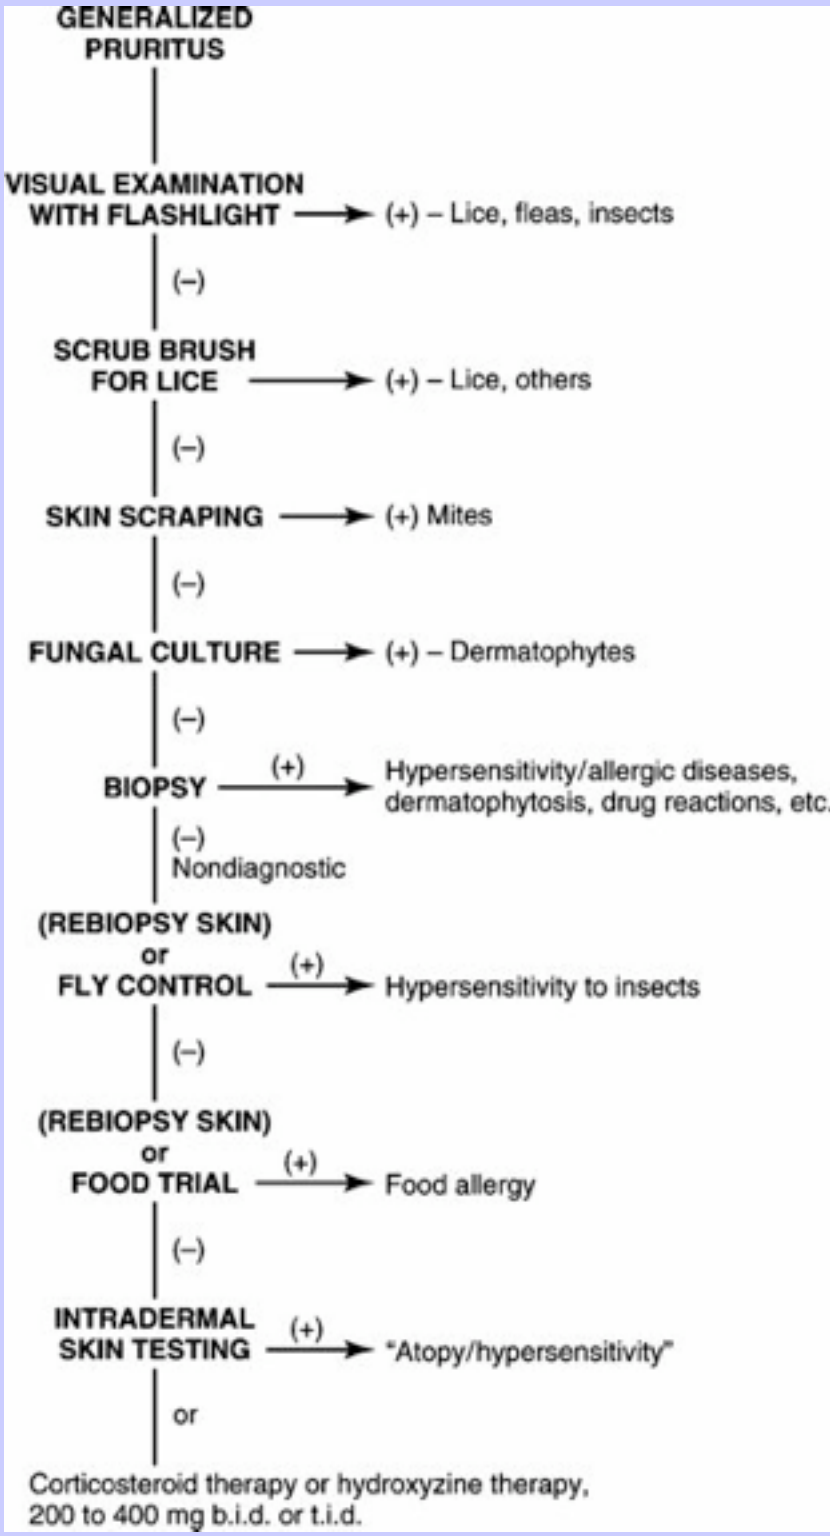
11.6.2 FOOD ALLERGY

Documented cases of feed-related hypersensitivity are rare in horses, and most information on this condition is based on anecdotal reports. Food hypersentitivity refers to an immune-mediated adverse reaction to a feedstuff unrelated to any physiologic effect of the feed. The pathogenesis of dietary hypersensitivity in horses is understood poorly but is believed to involve type I, type II, and type IV hypersensitivity reactions. The skin, respiratory tract, and gastrointestinal tract may be affected. The most commonly incriminated foods include potatoes, malt, beet pulp, buckwheat, fish meal, wheat, alfalfa, red and white clover, St. John's wort, chicory, glucose, barley, bran, oats, and tonics.[33]

Dermatologic manifestations of food allergy include generalized pruritus with or without papules, urticaria, and pruritus ani. Flatulence, loose stools, heaves, or asthma may accompany skin lesions.

Diagnosis is by eliminating the more common causes of pruritus in horses and by positive response to a food elimination trial (Figure 11-9). Hypoallergenic diets are individualized for each patient, and obtaining a thorough 679
dietary history from the owner is critical. One must identify any change in the diet (vitamin supplements, grains, 680
hays). A practical approach is to start by eliminating any supplements and concentrates from the diet. The trial should not include dusty feedstuffs because some horses can develop inhalant allergy to feedstuffs. One should feed oats and grass hay for 4 to 8 weeks and note whether a decrease in pruritus occurs. In the South, coastal Bermuda grass hay tends to be less allergenic than other types of hay. If the horse is notably less pruritic, one should reinstitute the previous diet to confirm that the pruritus is caused by a food allergy and that improvement was not coincidental. If food allergy is present, pruritus will return, and one should reinstitute the hypoallergenic diet until clinical signs subside. One identifies the offending substance by reintroducing one dietary item at a time each week and observing the horse for recurrence of clinical signs.

Figure 11-9 Flowchart for diagnosis of equine pruritic skin diseases.



11.6.3 CONTACT ALLERGY

True contact allergies are rare in horses, perhaps in part because the hair coat acts as a protective barrier. Irritant contact reactions are more common (see the following discussion). Contact allergies, when they occur, are type IV hypersensitivity reactions. Potential allergens are usually small molecules that penetrate the skin, bind to dermal collagen or carrier proteins, and are taken up by antigen-presenting cells (Langerhan's cells) in the dermis. On reexposure, an inflammatory response occurs that results in skin disease. Development of allergic contact reactions usually takes months to years.

Contact reactions most likely are related to pasture plants, changes in bedding material, insect repellents, topical medication, and tack items.[35,36] Parasiticides and bath oils applied as insect repellents are the most commonly identified causes of contact allergy. Repeated application of chemicals to the coat of sweating horses may predispose to development of a contact allergy because by compromising the protective barrier of the skin.

Clinical signs of contact allergy vary and depend on the duration of the allergic reaction. Erythema, swelling, oozing, pain, or pruritus develops within 2 to 3 days of application of the offending substance. If untreated, lesions often progress over weeks or months to alopecia, lichenification, and crusting. The distribution of the lesions may suggest the cause: legs (plants, bedding); face and muzzle (plants, bedding); face and trunk (tack); and face, ear, neck, and trunk (insect repellents).[36]

A definitive diagnosis is by provocative exposure or patch testing. Provocative exposure requires avoiding the suspect substance for 10 days or until lesions resolve, reexposing the horse to the substance, and noting recurrence of lesions or clinical signs over the next 7 to 10 days.[36] Provocative testing does not distinguish between an irritant reaction and an allergic reaction but does identify the offending substance. Patch testing requires the application of the suspect substance to an area of the skin for 48 to 72 hours. Plant material, bedding, or other particulate matter does not adhere well to the skin and is tested best under an occlusive dressing (closed patch test). For each test substance, one clips a 3-cm^2 area of hair on the thorax or dorsum, applies a small amount of the suspect substance to the skin, and covers the site with a gauze sponge bandage for 48 to 72 hours. One also should bandage a control site. On removing the bandages, one assesses the area for erythema, swelling, 680
induration, pain, and exudation. One should obtain biopsies of the control and test site(s) for histologic 681
confirmation of the diagnosis. One may apply liquid substances to the skin daily and not use an occlusive bandage.

Successful treatment requires accurate identification of the offending substance and avoidance. If this is not possible, one may prescribe short-term systemic corticosteroid therapy and mild cleansing shampoos.

11.7 Atopy

Atopy is an inherited dermatologic or respiratory condition in horses. Horses with atopy develop senstitizing antibodies, immunoglobulin E, to offending allergens. Allergens that have been implicated in this problem include molds, grasses, trees, fabrics, and dust. One or more of these allergens may be involved in an individual horse.[37]

Sensitizing antibodies cross-link mast cells, triggering release of inflammatory mediators with resultant inflammation in the affected target organ (i.e., skin or respiratory tract). In skin, pruritus is the end result.[32,37]

Arabian and Thoroughbred horses appear to be predisposed to develop atopy.[32] This breed predisposition suggests equine atopy may be an inherited condition. In one report a stallion and five of his offspring had atopy-induced urticaria.[38] The exact mode of inheritance is not known.

Atopy in horses is manifested as a seasonal to nonseasonal pruritic skin disease. Several types of skin lesions are observable, including alopecia, excoriations, crusts, scales, erythema, and hives (urticaria).[39] Urticaria is not always pruritic in horses. One can make a tentative diagnosis of atopy after eliminating other causes of pruritus and on positive response to exogenous corticosteroids.

The most effective way to confirm a diagnosis of equine atopy is by intradermal skin testing. One sedates the horse with xylazine at 0.05 mg/kg intravenously and clips a rectangular area on the lateral aspect of the neck. One then injects allergens known to cause allergic problems in a particular geographic area intradermally and denotes each site of allergen injection on the skin by a dot made with permanent marker. One reads the test at specific time intervals after injection: 15 minutes, 30 minutes, 4 to 6 hours, and 24 hours. One compares the negative (sterile saline) and positive (histamine 1:100,000 weight to volume) control reactions to reactions of the various allergens. The negative control is assigned an arbitrary grade of 0 and the positive control a grade of 4. One considers size of the wheal, firmness, redness, and shape when grading individual allergen reactions. Reactions greater than or equal to 2 are considered potentially significant. One must consider the history, clinical signs, and pollination times in the final determination of whether individual reactions are significant.

Certain allergens tend to cause many false-positive reactions, including alfalfa, corn, corn smut, grain dust, grain smut, black ants, mosquitoes, fire ants, *Rhizopus* spp., *Penicillium* spp., sheep wool epithelium, English plantain, red mulberry, black willow, mesquite, and dock sorrel. If a reaction occurs with one of these allergens and is inconsistent with the history and physical examination findings, it is probably an irritant reaction.

Horses with laminitis tend to have hyperresponsive immune systems and may be more likely to have false-positive skin test reactions than normal horses.[40] If the horse has had laminitis, one should interpret skin test results with care.

Drugs such as corticosteroids, antihistamines, fatty acids, and those that affect vasodilation such as acepromazine may interfere with skin test results and cause false-negative reactions. To avoid this situation, one should observe drug withdrawal times. Exact withdrawal times are extrapolated from small animal medicine and applied to horses. One should not administer long-acting injectable corticosteroids for 3 months before skin testing; oral or injectable dexamethasone, for at least 1 month before skin testing; and antihistamines, for 7 to 10 days before testing. A withdrawal time of 7 days is recommended for acepromazine.

Serum allergy testing has been recommended for diagnosis of atopy in horses. However, recent studies question the validity of this test. One study compared test results of three different serum allergy tests with intradermal skin test results in the same animal.[41] None of the three serum allergy tests reliably detected allergen hypersensitivity compared with results of the intradermal skin test. Serum allergy tests were not as sensitive as intradermal skin tests. At this time, in human and veterinary medicine, intradermal skin testing is considered the gold standard for confirming a diagnosis of atopy.[37]

Treatment of atopy should include hyposensitization whenever possible. One administers the offending allergens at a set amount and time to the horse. Many horses are treated with a maintenance schedule of 1 ml of a 20,000 protein nitrogen unit aqueous solution administered subcutaneously every 3 weeks. The exact mechanism of action for hyposensitization therapy is not known. Human beings with allergies tend to have a higher proportion of type 1

T helper cells compared with type 2 T helper cells.[42] After hyposensitization therapy the T helper cell populations shift toward normal. Other theories suggest that blocking antibodies are produced with hyposensitization. Regardless of the exact mechanism of action, hyposensitization therapy has been effective in human beings for more than 30 years.[43] The percentage of horses that respond to therapy varies and is thought to be similar to that in small animal medicine (59% to 86% effective).[43,44] Hyposensitization therapy may take 1 to 12 months (average 3 to 6 months) before it starts to work. One may use corticosteroids, antihistamines, and fatty acids in the period between initiation of hyposensitization therapy and expected response.

681
682

Corticosteroids are a mainstay of therapy for allergies but have been associated with a variety of adverse effects including polyuria, polydipsia, increased suspectibility to infection, mood changes, elevations in liver enzymes, and laminitis.[45] The most commonly used corticosteroids in equine dermatology are prednisolone, prednisone, and dexamethasone. Prednisone is converted to prednisolone in the liver. The dose for either of these two drugs for treating atopy is 0.5 to 1.5 mg/kg daily as an induction dose (usually 4 to 14 days) tapered to 0.2 to 0.5 mg/kg every 48 hours for maintenance. However, evidence indicates that prednisone is absorbed poorly from the intestine of many horses after oral administration. Therefore failure to respond to oral prednisone therapy does not confirm that a disorder is steroid nonresponsive. The recommended dose for dexamethasone is 0.04 to 0.2 mg/kg administered orally, intramuscularly, or intravenously every 24 to 48 hours for 4 to 7 days, decreasing to a maintance dose of 0.01 to 0.02 mg/kg every 48 hours.

Several antihistamines have been recommended for treating equine atopy. Hydroxyzine is recommended at 200 to 400 mg orally, regardless of body mass, every 12 hours orally or 1.5 mg/kg orally every 8 to 12 hours. Other antihistamines that have been used include chlorpheniramine maleate (0.26 mg/kg every 12 hours orally), diphenhydramine (0.75 to 1 mg/kg every 12 hours orally), doxepin hydrochloride (300 to 400 mg every 12 hours or 0.5 to 0.75 mg/kg every 12 hours), and pyrilamine maleate (0.8 to 1.32 mg/kg intravenously, intramuscularly, or subcutaneously; may be repeated in 6 to 12 hours if needed). The author has used all of these medications in horses and believes that hydroxyzine and chlorpheniramine maleate work most consistently in horses. Side effects associated with antihistamine use include sedation and behavior changes.

Fatty acids can act synergistically with steroids and antihistamines to decrease inflammation. ω-3 and ω-6 fatty acids seem to be most beneficial. They shift products of the arachidonic acid cascade from more inflammatory to less inflammatory mediators.[46]

Many fatty acid supplements are currently available, including Derm Caps ES (DVM Pharmaceuticals, Miami, Florida), Derm Caps 100 (DVM Pharmaceuticals), and Glänzen 3 (Horse Tech, Lawrence, Iowa). The first two products are available as a capsule or liquid, whereas the latter product is a powder to be sprinkled on food.

Dosage varies according to the fatty acid product used. The dosage for Derm Caps ES is 5 capsules every 12 hours; the dosage for Derm Caps 100 is 2 to 3 capsules every 12 hours. The dosage for the Glanzen 3 is 2 to 6 oz powder sprinkled on the food per day (not to exceed 6 oz per day). This product also contains biotin and other vitamins and minerals.

Topical treatments may be a useful adjunct therapy for horses with atopy. Various shampoos, lotions, and sprays marketed for use in small animals may be of benefit in horses. Antipruritic ingredients may include oatmeal, aloe, pramoxine, and hydrocortisone. Combination products may be most effective. The author prefers the Relief products marketed by DVM Pharmaceuticals of Miami, Florida, that contain oatmeal and pramoxine. These products may be used daily or weekly.

11.8 Cutaneous Drug Reactions

Cutaneous drug reactions in horses are rare and can mimic any known skin disease. Drug reactions are believed to involve type I, II, III, or IV hypersensitivity reactions. Any therapeutic agent administered by any route may cause a drug reaction. The most commonly incriminated drugs are penicillin, streptomycin, oxytetracycline, neomycin, chloramphenicol, sulfonamides, phenothiazines, phenylbutazone, guaifenesin, aspirin, and glucocorticoids. Clinical signs vary, and pruritus may or may not be present. Urticaria is a commonly observed skin reaction. Less commonly, mucocutaneous ulceration or vesiculation may be present.

Diagnosis of a drug reaction depends on an accurate medication history. Skin biopsies may be helpful in supporting a clinical diagnosis. The most commonly reported patterns of inflammation are perivascular dermatitis and intraepidermal or subepidermal vesicular dermatitis.[36] One can confirm the diagnosis by provocative challenge, but this may lead to anaphylaxis or death and therefore is not recommended.

Treatment requires removal of the offending drug, symptomatic therapy, and avoiding related compounds. Drugs reactions, in general, do not respond well to glucocorticoids. A drug reaction usually subsides within 2 to 3 weeks but may last for months.

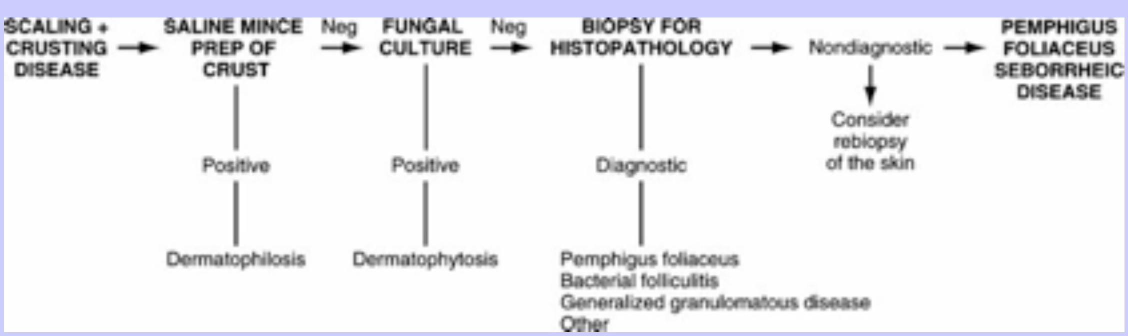
11.9 Causes Of Pruritus: Crusting And Exfoliative Dermatoses

Dermatophytosis and bacterial skin infections may cause pruritus in horses. They are recognized more commonly in the field as crusting or exfoliative dermatoses.

11.9.1 COMMON CAUSES OF SCALING AND CRUSTING DERMATOSES

Exfoliative dermatoses in horses have a wide range of causes. Historical and physical findings are important in differentiating these diseases. To make a diagnosis in difficult cases may require skin scrapings, fungal cultures, 682
bacterial cultures, mince preparations of crusts for cytologic examination of dermatophilosis, and skin biopsies. 683
If cost constraints are present, the most useful diagnostic test is a carefully obtained skin biopsy. Not scrubbing or preparing the skin in any way before obtaining skin biopsy specimens is critical. In addition, one should take extreme care to collect the crust when obtaining a skin biopsy from a horse with exfoliative skin disease. In many instances, one obtains the causative agent or evidence of a definitive diagnosis from histopathologic examination of the crust. Figure 11-10 shows a simplified approach to the diagnosis of exfoliative dermatoses.

Figure 11-10 Flowchart for diagnosis of equine scaling and crusting diseases.



11.9.2 INFECTIOUS CAUSES OF EXFOLIATION

11.9.2.1 Dermatophilosis (Rain Scald)

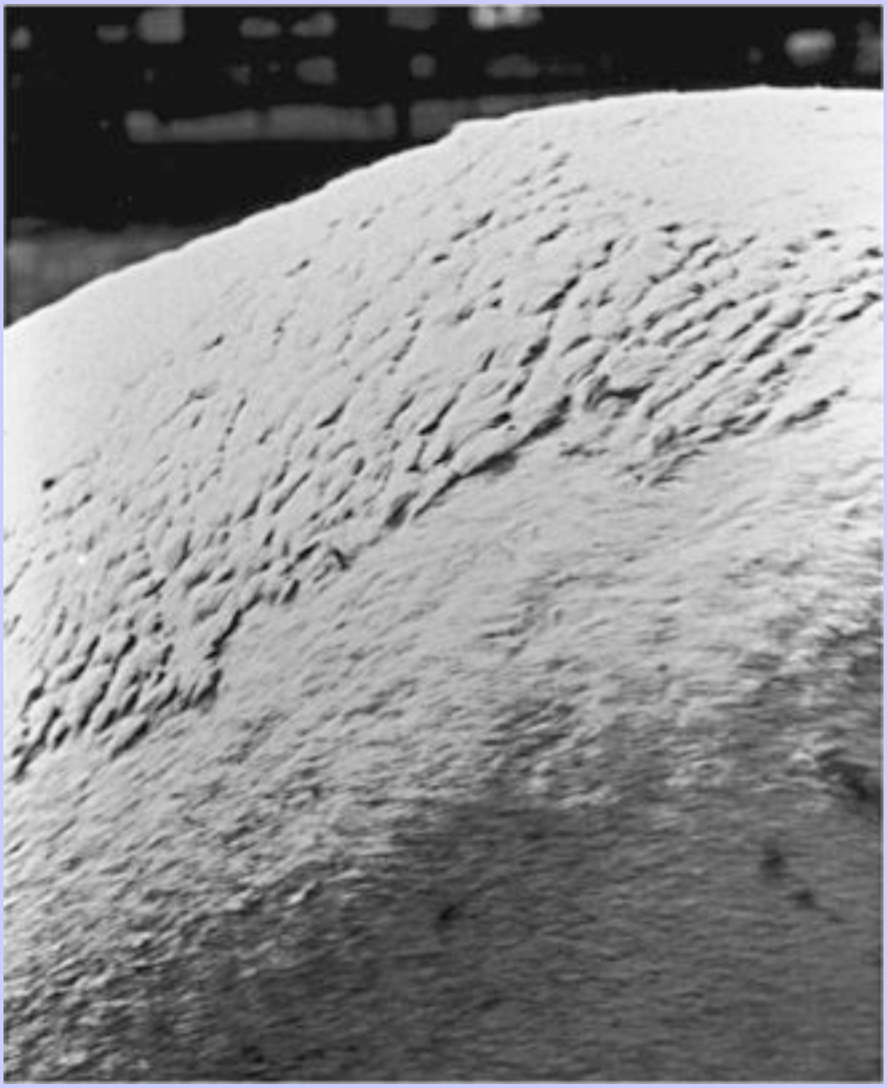
Dermatophilosis is a bacterial skin disease of horses and other large animals caused by the gram-positive, facultative anaerobic actinomycete *Dermatophilus congolensis*. The normal habitat of the organism is unknown, but the organism is thought to exist in a quiescent state on carrier animals until conditions are optimal for proliferation.[47] Whether carrier animals act as reservoirs of infection for other animals is unknown.

The development of lesions depends on chronic moisture and skin damage.[47,48] The organism cannot penetrate intact healthy skin, and moisture is required for release of zoospores. The skin can be damaged from chronic maceration caused by moisture, biting flies, vegetation, or underlying pruritic skin diseases. Chronic moisture is more conducive to the growth of the organism than intermittent but heavy rainfall. When these two prerequisites (moisture and trauma) are met, the organism multiplies. Moisture induces release of infective, motile, flagellated zoospores. These organisms are attracted to low concentrations of carbon dioxide and repelled by high concentrations of carbon dioxide. As the organism multiplies and inflammatory cells migrate into the area, the carbon dioxide concentration in the skin increases and zoospores migrate toward the surface of the skin in search of a more suitable environment. The organism again multiplies and numbers increase. This cycle repeats until layering, crusting, and matting of the hair coat results. Zoospores remain viable in crusts at ambient temperatures of 28° to 31° C for up to 42 months.[47]

Clinical signs of dermatophilosis can develop within 24 hours. The disease has a follicular orientation, and lesions appear as crusted, moist mats of hair that can resemble small paintbrushes. Under fresh crusts, the skin is soft, exudative, and yellow-tinged. Exudative crusted lesions tend to occur on the back, gluteal area, face, neck, and distal extremities (Figure 11-11). Lesions on the limbs may cause pain, swelling, and erythema, especially in white or lightly pigmented areas. Racehorses or horses in training commonly develop abrasions on the cranial surface of the hindlegs. These lesions are prime sites for infection. Severely affected horses may be febrile, depressed, lethargic, and anorectic and have a regional lymphadenopathy.

Dermatophilosis is diagnosed by demonstration of the organism by cytologic examination of the crust or by histologic examination of a skin biopsy specimen. One can make dermatophilosis preparations from dried or fresh crusts or from direct smears of exudate. One finely minces dried crusts in a few drops of sterile saline, allowing the preparation to dry for 45 minutes and then staining it. One may use a fast Giemsa, Diff Quik, or Gram stain for direct smears or dried mince preparations. The organism is visualized best under 1000× oil immersion and appears as fine-branching multiseptate hyphae with transverse and longitudinally arranged cocci (railroad track appearance; Figure 11-12). When one collects a skin biopsy from a horse with suspected dermatophilosis, submitting a specimen with the crust attached to the skin or hairs is important. Key histologic findings include folliculitis, intraepidermal pustules, intradermal edema, and alternating layers of parakeratotic (epidermal cells with retained nuclei) and orthokeratotic (keratinized epidermal cells without nuclei) hyperkeratosis with leukocyte debris.[48] The organism often is found only in crusts. 683

Figure 11-11 Horse with matting of coat caused by dermatophilosis.



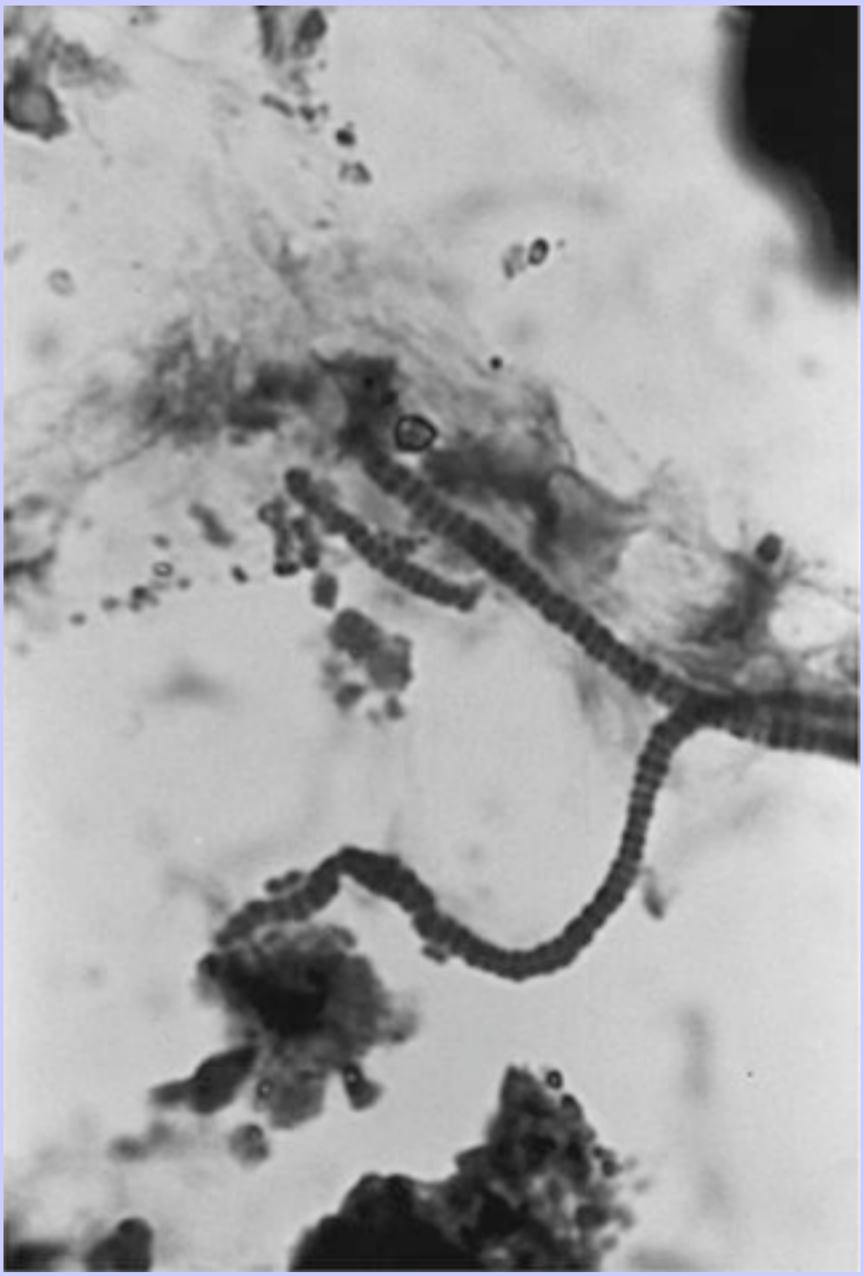
One may treat horses with mild infections with topical therapy alone. One gently should soak and remove crusts using a mild antibacterial shampoo such as chlorhexidine or benzoyl peroxide. Some horses for which this is difficult or painful may require sedation. One should dry the horse with towels and apply a topical antibacterial sponge-on dip (chlorhexidine 1:32 dilution of 2% stock solution, or lime sulfur 1:32 dilution of stock solution). Another option is a commercially prepared chlorhexidene 2% lotion (Resi-Chlor, Vibrac, Fort Worth, Texas) after bathing with an antibacterial shampoo. This formulation is a leave-on product with residual properties. Daily shampoo therapy should continue for 5 to 7 days until healing is evident, then twice weekly until all lesions have resolved. Horses with lesions on the muzzle may benefit from a topical cream with or without corticosteroids. Severely affected animals may benefit greatly from systemic antibiotics, such as procaine penicillin at 22,000 IU/kg intramuscularly twice daily for 5 to 7 days. Trimethoprim sulfa at 10 to 15 mg/kg orally twice daily for 5 to 7 days also may be effective. In either case, one should eliminate exposure to excessive moisture and skin trauma.

11.9.2.2

Dermatophytosis (Ringworm)

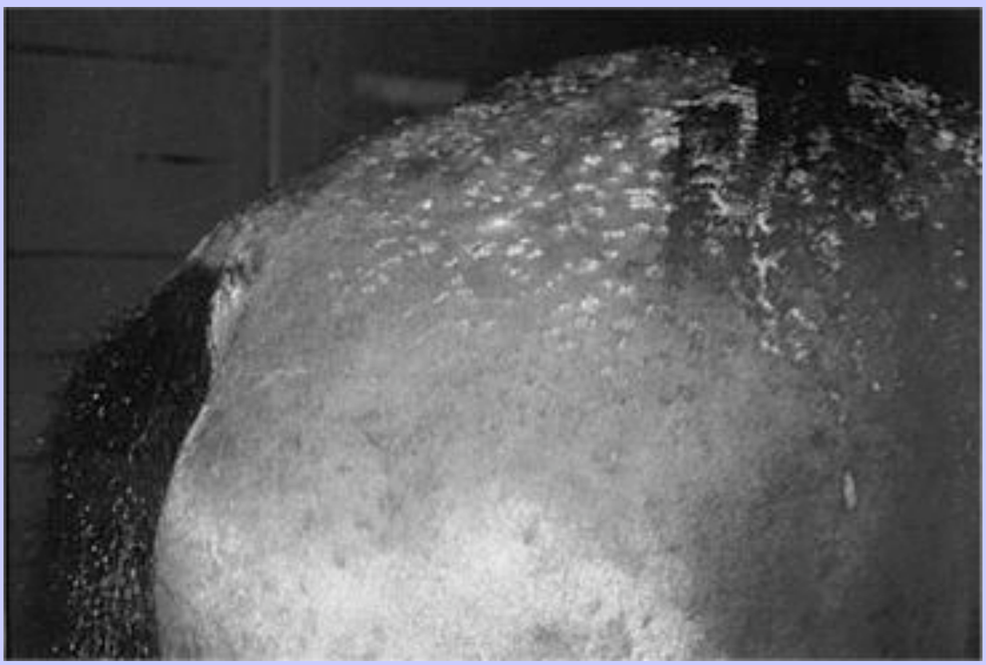
Dermatophytosis is the most common contagious skin disease in the horse. *Trichophyton equinum, Trichophyton mentagrophytes, Microsporum gypseum,* and *Microsporum canis* are the most frequent isolates. [49] The infection is self-limiting but may affect the function of the horse seriously and is of zoonotic importance.

Figure 11-12 Microscopic appearance of *Dermatophilus congolensis.*



Dermatophytes are transmitted by direct contact with an infected host or by indirect contact with contaminated fomites or the environment. Illness, poor nutrition, overcrowding, age (young or old immunosuppressed individuals), and stress predispose horses to infection. Chronic moisture from sweating or the environment damages the protective barrier of the skin, enhancing the opportunity for infection. When fungal spores contact the hair coat, the spores may be removed mechanically, may be unable to compete with the normal flora of the skin, or may remain on the coat in a dormant state until conditions are optimal for infection. Dermatophytes invade keratin of the epidermis and hair with the aid of enzymes that are allergenic to the host. Dermatophytosis is considered a biologic contact dermatitis.[49] The incubation period is usually several weeks. During this time, fungi invade the epidermal keratin, hair follicles, and the hair shaft itself. The epidermis responds to the intruder by increasing epidermal cell turnover in an effort to remove the fungi mechanically. 684 Clinically, the response is scaling. Hair shaft integrity is compromised, and hairs fall out or are fractured 685 easily, resulting in areas of alopecia characteristic of the disease. Infection is eliminated from a particular hair on shedding or as it enters the telogen stage, or the dermatophyte elicits an inflammatory response.

Figure 11-13 Dermatophytosis. The popular eruption on the advancing edge of lesions is notable.

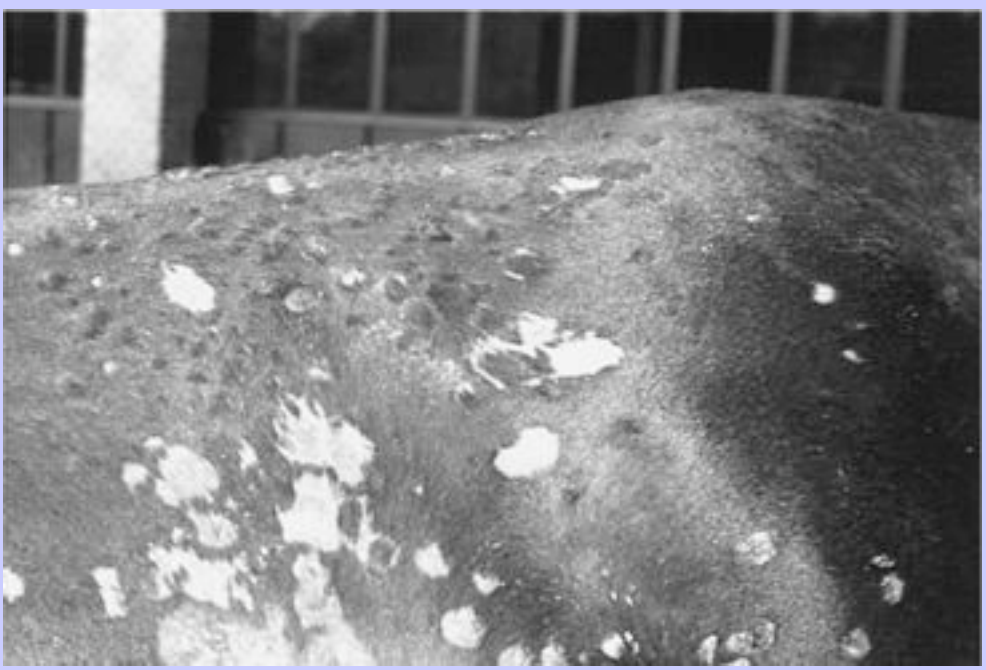


Clinical signs of dermatophytosis, including pain and pruritus, vary. The infection is follicular in distribution, and early lesions often begin as a papular eruption with erect hairs (Figure 11-13). Urticarial eruption may occur 24 to 72 hours before the owner notices the papules.[50] Lesions rapidly progress to crusted papules that spread circumferentially. The classic lesion is a circular patch of alopecia with stubbly hairs on the margin and variable amounts of scaling (Figure 11-14). Erythema and hyperpigmentation may be present. In rare instances, dermatophytosis may present as generalized scaling without significant hair loss. If the dermatophytosis causes follicular rupture, nodules, and ulcers, or a kerion reaction (inflammatory

dermatophyte infection that may resemble an abscess) may develop. Lesions are most common in areas where tack contacts the skin but may be limited to the posterior pastern.

Diagnosis is by demonstration and identification of the organism. Wood's lamp examinations are not useful for logistic reasons and, more importantly, because few cases of equine dermatophytosis are caused by *M. canis*. Direct examination of hair and scale is useful but requires special training. The most reliable tests are fungal culture and skin biopsy. The details of superficial fungal culture techniques have been reviewed elsewhere.[51,52] One should collect hairs for culture from the periphery of a newly developing lesion. Avoiding areas that may have been treated previously is critical. One should wipe the area gently with an alcohol swab before collecting hair samples to minimize growth of contaminants, should pluck hairs in the direction of growth, and transport them to the laboratory or clinic in a paper envelope for inoculation on dermatophyte test medium or Sab-Duets plates (Bacti-Labs, Mountain View, California), the commercial fungal culture media preferred by most veterinary dermatologists. Each plate contains Sabouraud's glucose medium and dermatophyte test medium. Using both media plates greatly enhances the culturing of suspect organisms. *Trichophyton* species isolation improves if one adds a few drops of B vitamin complex to the surface of the media and incubates the plate at 37° C. Because *T. equinum* is supposed to be one of the more common equine dermatophytes, one should add the B vitamin complex to all equine fungal cultures. One should select skin biopsy sites with care and should not scrub or wipe the area before sampling. Early lesions with crusts are ideal. Histologic findings include folliculitis, perifolliculitis, and furunculosis; superficial perivascular dermatitis with ortho- or parakeratosis; and intraepidermal vesicular or pustular dermatitis. Septate fungal hyphae and oval spores may be present in the superficial keratin or hair follicle.[51]

Figure 11-14 Classic signs of dermatophytosis (ringworm).



Dermatophytosis is a self-limiting disease, and most cases heal spontaneously within 1 to 6 months. Treatment strongly is advised to minimize contagion to other animals and human beings. In horses, antifungal shampoos and sponge-on dips are the treatment of choice. The author has found the most effective topical treatment

combination to be weekly bathing with a shampoo that contains 2% miconazole followed by a lime sulfur dip (Lym-Dyp, DVM Pharmaceuticals, Miami, Florida) for 4 to 8 weeks. Systemic antifungal drugs, such as griseofulvin (50 mg/kg orally once daily) or itraconazole (5 to 10 mg/kg orally once daily) are effective but expensive. In instances in which treating an infected herd is necessary or desirable, itraconazole at 5 to 10 mg/kg orally once daily for 15 days aborts the infection. Concurrent topical therapy with lime sulfur is necessary.

Elimination of dermatophytosis from single or multiple horse barns requires elimination of the organism from 685
infected hosts and decontamination of the environment. Box 11-3 summarizes one approach to treatment. 686
Commercial antifungal vaccines for equine dermatophytosis are not available in the United States. Autogenous vaccines are not recommended at this time because of lack of information on their efficacy and potential for serious adverse effects, including sterile abscesses, hypersensitivity reactions, generalized anaphylaxis, and death.

11.9.2.3 Bacterial Infections

Bacterial folliculitis in horses is caused most commonly by *Staphyloccoccus* spp. *Streptococcal* spp. infections also may occur. Infections most frequently occur in the summer when heat, moisture, increased insect populations, and increased use of the horse act in concert as predisposing factors.

The pathogenesis of bacterial folliculitis in the horse is similar to that in other animals. The causative agents normally are found on the host; when the natural protective barrier of the skin is compromised, bacteria invade and multiply within hair follicles. Infection results in inflammation, destruction of the hair follicle, and shedding of the hair. As the infection spreads, lesions enlarge. If hair follicles rupture, furunculosis and deep pyoderma may result.

Clinically, bacterial folliculitis may be indistinguishable from dermatophytosis. Bacterial lesions are much more likely to be painful and are only rarely pruritic. Infection is most common in the saddle and tack area but may be limited to the pastern area. Deep pyoderma of the tail base also occurs.

Definitive diagnosis is made best by cytologic examination, bacterial culture, and skin biopsy. Differentiating bacterial folliculitis from dermatophytosis is important. Skin biopsy reveals varying degrees of folliculitis, intraepidermal pustules, and perivascular inflammation. Neutrophils are the primary inflammatory cell. Keratinocytes often show intracellular edema; parakeratosis and orthokeratosis are common in the crust. Special stains often reveal bacteria within the crusts and hair follicles.

Treatment depends on severity of the clinical signs. Mild infections may be self-limiting but benefit from topical therapy. Severe cases require daily topical antibacterial shampoos with benzoyl peroxide or chlorhexidine and oral antibiotics. Ideally, one should base systemic antibiotic therapy on results of culture and sensitivity testing, but procaine penicillin at 22,000 IU/kg intramuscularly every 12 hours until resolution of clinical signs is usually effective.[51] A minimum of 10 to 14 days of therapy is recommended.

11.9.3 NUTRITIONAL CAUSES OF EXFOLIATION

Nutritional deficiencies are rare in horses, and much of this information has been extrapolated from work in other species or experimentally induced deficiencies.

11.9.3.1

BOX 11-3 TREATMENT OF EQUINE DERMATOPHYTOSIS (RINGWORM, FUNGUS) IN MULTIPLE HORSES

In the treatment of ringworm or superficial fungal infections of the skin, one must accomplish three things:

1. Kill the fungus on the animal to stop progression of the disease.
2. Kill the fungus on the animal to prevent spread to other animals, human beings, and the environment.
3. Decontaminate the environment.

The following suggestions have been helpful when treating outbreaks in the multiple-horse barn. One should keep in mind that fungal infections may take 6 to 8 weeks to heal completely.

1. *Isolate* all affected horses from normal horses.
2. Treat the barn by cleaning out all bedding and spraying stalls and exposed surfaces with 1:10 dilution of household bleach.
3. Treat all affected horses daily with lime sulfur sponge-on (4 oz/gal) for 7 days and then once weekly. Treating the *entire body* of each horse, not just the affected areas, is vital. One should allow sponge-on preparations to dry on the horse and should not bathe horses between treatments.
4. Use individual brushes and tack for each horse. Disinfect brushes and tack frequently. Do not transfer equipment between horses.
5. Blankets used with household bleach should be disinfected twice weekly or more often. *Not* using blankets or sheets is best to avoid enhancing the spread of the lesions.
6. Ideally, the persons who handle affected horses should not handle normal horses. If this is not possible, one should handle normal horses first and then affected horses. Washing *well* between animals with a chlorhexidine scrub is important.
7. Ringworm is contagious to other animals and human beings; handlers should be careful to wash well and report the development of any lesions. If possible, handlers should wear gloves when handling affected horses.
8. Ideally, horses affected with ringworm should be rested from training or riding until lesions are gone. Continued riding or training may contribute to skin microtrauma and spread of infection.

Modified from client education handouts used at the College of Veterinary Medicine, University of Florida, and the School of Veterinary Medicine, University of Wisconsin.

686

687

11.9.3.2

Protein

Protein deficiency may occur in horses with fever, dysphagia, burns, proteinuria, liver disease, gastrointestinal diseases, or any disease in which metabolic demand increases and production of protein decreases. The skin uses 25% to 30% of the daily protein intake for hair production and maintenance of the epidermis,[53] a

requirement that may increase fivefold in disease states. In experimental deficiencies created in ruminants and laboratory animals, protein-deficient animals develop dry, dull, brittle, thin hair. Prolonged shedding also occurs.[54] Presumably, horses with protein-deficient diets would manifest similar clinical signs.

11.9.3.3 Zinc

Naturally occurring zinc deficiencies have not been reported in horses. Classically, this deficiency appears as crusting skin disease. Experimentally induced zinc deficiencies in foals resulted in alopecia, dense scaling on the lower limb that progressed to the trunk, inappetence, decreased growth rate, and decreased tissue and serum zinc concentrations.[54] Definitive diagnosis is by observing histologic lesions compatible with zinc deficiency (diffuse epidermal and follicular parakeratosis) and response to oral supplementation with zinc sulfate at 10 mg/kg once daily. A significant response usually occurs within 2 to 3 weeks, and therapy may or may not be lifelong.

11.9.3.4 Iodine

Suspected iodism caused by excessive supplementation therapeutically or in feeds has been reported in horses.[55] Noncutaneous signs include cough, lacrimation, nasal discharge, and joint pain. Severe dry seborrhea with or without dorsal alopecia is also present. No treatment is necessary and horses recover spontaneously on removal of the source of excess iodine.

11.9.4 PARASITIC CAUSES OF EXFOLIATION

Insect hypersensitivities (discussed earlier) are the most common parasitic cause of exfoliation in horses. The major differentiating feature is the presence of pruritus, lack of circumferentially spreading lesion, and the absence of pain. Skin biopsy findings of superficial or deep eosinophilic perivascular dermatitis with or without collagen degeneration suggest insect hypersensitivity.

11.9.5 IMMUNOLOGIC CAUSES OF EXFOLIATION: PEMPHIGUS FOLIACEUS

Pemphigus foliaceus is a rare autoimmune skin disease that results in severe crusting and matting of the hair coat. An autoantibody against the glycocalyx of keratinocytes results in the release and activation of keratinocyte proteolytic enzymes into the intercellular space. The glycocalyx is hydrolyzed and intercellular cohesion is lost, leading to acantholysis.[56]

Pemphigus foliaceus has no age or sex predilection. Appaloosa horses appear to be predisposed to developing pemphigus foliaceus.[57] Lesions usually begin on the face and limbs and may take weeks or months before becoming generalized. In some horses the disease affects only the coronary band. One rarely observes the primary lesion, a subcorneal pustule, because of the hair coat of the horse. The most common clinical presentation is severe matting and crusting of the coat with oozing of serum from the skin (Figure 11-15). Most horses are depressed and show signs of systemic illness. Swelling and pain of the distal extremities, in addition to lameness are common. Pruritus and pain on the trunk, ventral edema, and regional or generalized lymphadenopathy vary.

Definitive diagnosis is by routine histologic examination of a skin biopsy specimen. Submitting a skin biopsy with intact crusts attached to the underlying skin or hairs is critical. Histologically, pemphigus foliaceus is

characterized by intragranular to subcorneal acantholysis. One often observes layered rafts of acantholytic cells within crusts interspersed among neutophils.[57] Direct immunofluorescence is unreliable, but if positive reveals diffuse intercellular fluorescence. One may make a tentative diagnosis of pemphigus foliaceus based on impression smears of the content of intact pustules or the underside of exudative crusts (Figure 11-16). Rafts of deeply basophilic acantholytic cells and nondegenerate neutrophils are highly suggestive of this disease.

Pemphigus foliaceus in horses less than 1 year of age is usually self-limiting. Spontaneous remission is common in foals, and they often do not require long-term therapy. Because treatment is difficult and often unrewarding in adults, many owners elect euthanasia. Remission and control of the disease is induced with prednisone or prednisolone at 1 mg/kg orally every 12 hours until no new lesions develop, which usually occurs within 7 to 10 days, at which point alternate-day therapy continues at the same dose. If the horse does not respond to prednisone, one should attempt daily therapy with dexamethasone because of potential problems with absorption of prednisone given orally in some horses. Maintaining clinical normalcy with prednisone therapy alone is difficult, and one may have to add adjuvant immunosuppressive agents to the treatment program. Even in cases in which prednisone therapy is effective, the potential for laminitis and immunosuppression warrant the use of other agents. Chrysotherapy (gold salts) has been used in horses but is expensive.[58,59] One administers two doses of aurothioglucose (Solganal, Schering Corp., Kenilworth, New Jersey) 1 week apart intramuscularly, 20 and 40 mg, respectively. If one observes no adverse effects (stomatitis, urticaria, sloughing of skin, blood dyscrasia), one begins weekly therapy at 1 mg/kg intramuscularly until observing a response (6 to 12 weeks). One tailors maintenance therapy to the individual animal, which may involve biweekly or monthly therapy. Complete remission of clinical signs may not be possible to achieve even with combination therapy. The most common adverse effects of aurothioglucose therapy in human beings, dogs, and cats are immune-mediated thrombocytopenia and proteinuria. Presumably, these could occur in the horse. Weekly performance of a complete blood count and urinalysis is recommended for the first month and then monthly if one observes no abnormalities.

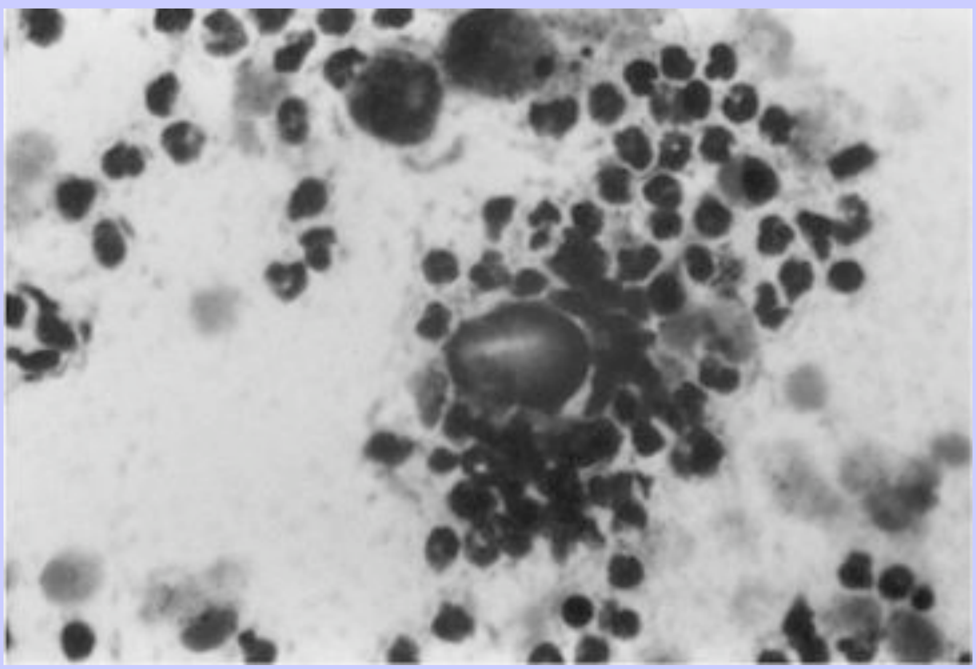
11.9.6 IRRITANT CONTACT DERMATITIS

Irritant contact dermatitis is fairly common in horses. This reaction differs from allergic contact dermatitis because the offending substance invariably causes a reaction if left in contact with the skin; prior sensitization is not needed.

The mechanism of irritant contact reaction depends on the causative chemical, but moisture and tissue maceration are important predisposing factors. Common irritating substances include feces, urine, wound secretions, caustic substances, crude oil, diesel oil, turpentine, blisters, leg sweats, improperly used insecticides, fly wipes, concentrated disinfectants, irritating plants, and soiled bedding.[60]

No age, sex, or breed predilection exists for irritant contact dermatitis.[60–62] Direct contact with the offending substance is required for irritant reactions to occur. Acute lesions are often erythematous, vesiculated, erosive or ulcerated, and painful. As the condition continues, necrosis, crusting, scaling, and hair loss occur. Leukoderma 688
and leukotrichia are common and may be permanent. Prutitus and pain vary. 689

Figure 11-16 Cytologic appearance of a touch preparation from a lesion of pemphigus. Rounded cells (acanthocytes) are notable.



Diagnosis is from the history, clinical signs, and inspection of the environment of the horse. Provocative testing is useful in identifying and confirming the causative agent as long as the risk is minimal to the horse. Histologic examination of skin reveals necrosis, spongiotic vesicles, and ulceration.

Treatment requires identification and removal of the offending substance. One should wash affected areas daily with copious amounts of water and apply topical 0.5% chlorhexidine soaks. Astringent topical solutions, for

example, aluminum acetate (Domeboro, available as an over-the-counter preparation), may be beneficial but often cause pain or delay wound healing. Topical antimicrobial creams free of corticosteroids may promote healing. Healing usually is rapid once the irritant is removed.

11.9.7 ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis has been discussed. An important note is that allergic contact dermatitis may cause scaling and crusting in addition to pruritus. Lesions usually are distributed in a pattern that reflects the offending substance.

11.9.8 PHOTODERMATITIS

Photodermatitis is caused directly by sunburn or indirectly by photoallergy or photosensitization.

11.9.8.1 Sunburn

Sunburn is a phototoxic reaction caused by excessive exposure to ultraviolet B light. Horses with white or light skin or hair are at risk. Affected areas become erythematous and scaly. If sunburn is severe, necrosis and exudation may occur. Diagnosis is based on history and clinical signs. Topical glucocorticoid creams alleviate pain, but excessive use has the potential to cause minor side effects (depigmentation, failure, or slowing of hair regrowth) or possibly serious side effects (laminitis) because these drugs are absorbed systemically. Stabling horses during periods of intense sunlight and application of water-repellent sunscreens may be helpful.

11.9.8.2 Photoallergy

Photoallergy is believed to be caused by contact with a chemical or plant (species unknown) and ultraviolet light. The condition is observed most commonly on white muzzles and extremities of horses housed on pasture containing clover, particularly alsike clover. Erythema, vesicles, and crusts develop. Diagnosis is by clinical findings. If one cannot identify the offending substance and remove it from the environment, then horses should be stabled during daylight, if possible, to minimize exposure to the offending substance.

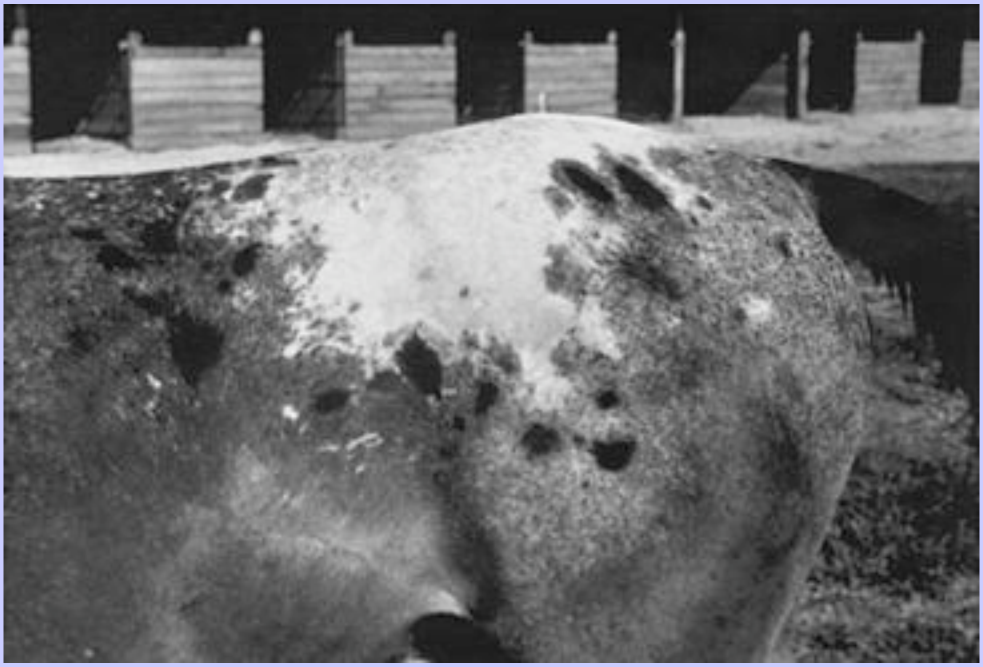
11.9.8.3 Photosensitization

Photosensitization may develop as a result of hepatogenous photosensitization; aberrant pigmentation formation; or ingestion, injection, or topical application of a primary photodynamic agent.[60,63] Examples of plants known to cause primary photosensitization in horses include St. John's wort, buckwheat, perennial rye grass, and burr trefoil. Chemicals that may cause primary photosensitization include phenothiazine, thiazide, acriflavine, rose bengal, methylene blue, sulfonamides, and tetracyclines. Plants, fungi, infection, neoplasms, and certain chemicals have been associated with hepatogenous photosensitization in horses. Plants that may cause equine hepatogenous photosensitization are burning bush or fireweed, ngaio tree, rape or kale, heliotrope, ragworts, tarweed or fiddleneck, and *Crotalaria* or rattleweed. Fungi that can induce hepatogenous photosensitization in horses include blue-green algae and *Phomopsis leptostromiformis* (on lupins). A detailed discussion on the pathogenesis of liver disease and its association with cutaneous photosensitization is included elsewhere in this text.

Regardless of the source of the photodynamic agent, the pathophysiology of skin disease is similar. Photodynamic agents are deposited in the skin and absorb energy when exposed to sunlight. These molecules are elevated to a high energy state and, in the presence of oxygen, produce free radicals that damage cell membranes. Lysosomes and other organelles release hydrolytic enzymes and other mediators of inflammation.

Lesions are most common in white or lightly pigmented areas but have been observed to extend into dark-colored areas.[51,60] Eyelids, lips, face, perineum, and coronary bands commonly are affected. Usually an acute onset of erythema, edema, pruritus, and pain occurs. Vesicles and bullae may develop (Figure 11-17). Necrosis, ulceration, and crusting often occur.

Figure 11-17 Horse with photosensitization.



689

690

Diagnosis is based on clinical signs, history, and laboratory tests. One should perform liver function tests regardless of whether the horse is showing clinical signs of hepatic disease.

Treatment requires identification of the underlying cause. Prognosis varies in horses with liver disease. Therapy requires removal of the offending substance, avoidance of sunlight, and topical or systemic glucocorticoids.[51]

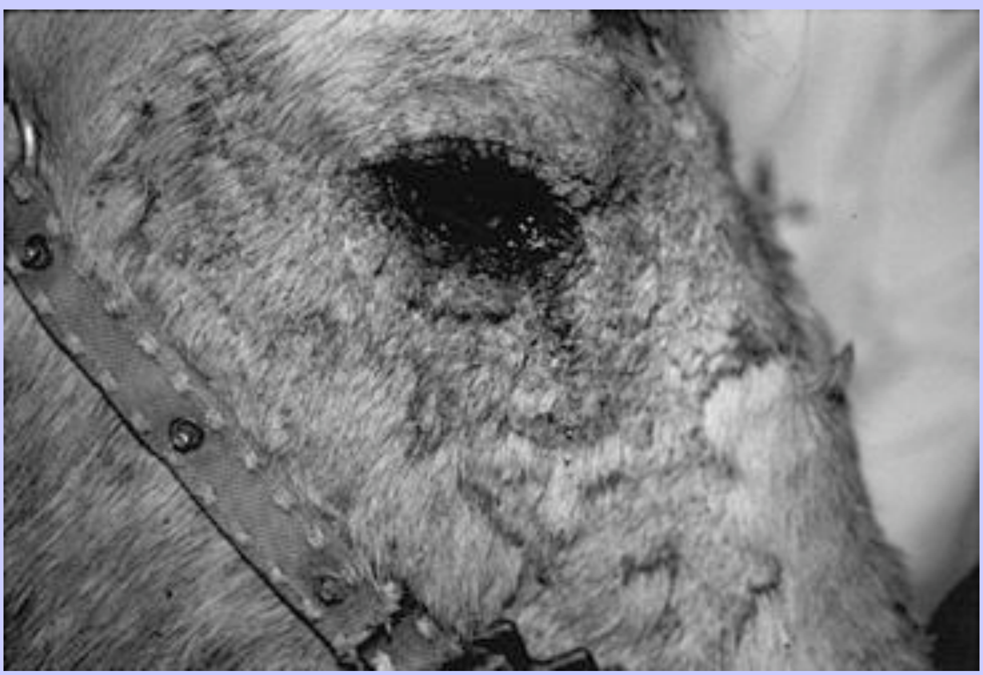
11.9.9 SEBORRHEA AND LOCALIZED DISORDERS OF KERATINIZATION AS CAUSES OF SCALING AND CRUSTING

11.9.9.1 Seborrhea

Seborrhea is a descriptive term for excessive scaling and crusting. The condition may or may not result from excessive sebum production. Most seborrheic skin conditions are secondary, resulting from dermatophytosis, dermatophilosis, or parasitic or bacterial skin diseases. The natural response of the skin to insult is proliferation, as a mechanism by which to remove an offending organism or as a result of inflammation. Primary seborrhea is a disorder of keratinization in which epidermal cell turnover time and basal cell proliferation increase. Genetic factors may control these mechanisms. Secondary seborrhea, the most common form of seborrhea, can occur in any inflammatory, infectious, or parasitic disease.

Idiopathic or primary seborrhea in horses may be generalized or localized to the tail and mane. No age, sex, or breed predilection exists. Generalized seborrhea appears clinically as diffuse matting of the coat. The texture of the coat may be oily and thick; adherent crusts may be removed easily. Oily or dry scales are present at the base of the hairs. Lesions usually are generalized and involve the face and legs (Figure 11-18). The animal is odoriferous and is not usually pruritic. Seborrhea of the mane and tail is common and presents as crusts or scales attached to the bases of hairs. Pain and inflammation are generally absent.

Figure 11-18 Horse with primary seborrhea.



Primary seborrhea is a diagnosis of exclusion. Severe generalized seborrhea must be differentiated from pemphigus foliaceus. One should perform skin scrapings, fungal cultures, dermatophilosis preparations, and skin biopsies on all suspect cases. Skin biopsies may help in determining whether primary or secondary

seborrhea is present.[64] In early cases of generalized equine seborrhea involving little secondary inflammation, skin biopsy findings strongly suggest a primary keratinization disorder. The noncornified epidermis is not hyperplastic (thickened), but a significant orthokeratotic hyperkeratosis is attached to an epidermis of normal thickness. The superficial dermis shows only a noncornified epidermis, suggesting a keratinization defect. In cases with secondary inflammation or in which the seborrheic condition is more long-standing, one may not interpret the biopsy findings as easily. The cornified epidermis is acanthotic (thickened) with significant orthokeratosis or parakeratotic hyperkeratosis. Superficial perivascular inflammation often is present in the superficial dermis.

Treatment of seborrhea involves eliminating the predisposing cause. Primary seborrhea is usually incurable, and management is symptomatic with topical therapy. The owner usually can manage seborrheic condition satisfactorily with antiseborrheic shampoos. The owner should wash the horse with a cleansing shampoo before using a medicated shampoo. This removes excess dirt and scale, improves efficacy of the medicated shampoo, and decreases the amount of medicated shampoo needed, minimizing potential for a contact reaction. The owner may use several brands of shampoo before finding a suitable shampoo for an individual patient. In general, dry seborrhea responds best to sulfur-based shampoos and oily seborrhea to tar-based shampoos. Benzoyl peroxide shampoos also work well in cases of oily seborrhea. Antiseborrheic shampoos formulated for small animals work well for horses but may be expensive. The owner should avoid human shampoos because these products are often more expensive than veterinary products and lather excessively, making rinsing difficult. Owners should allow the antiseborrheic shampoo to contact the coat for 10 to 15 minute before rinsing. Thoroughly rinsing the horse is important, especially in the axillary and inguinal region, because shampoo residues irritate the skin. Initially, owners may need to shampoo the horse daily for 1 to 2 weeks. After the coat of the horse is normal, the owner may decrease shampooing to twice a week but must realize that therapy is lifelong. If shampoo therapy dries the coat and worsens dry seborrhea, the owner may use a moisturizing spray or lotion.

11.9.9.2 Cannon Keratosis

Cannon keratosis is an idiopathic skin disease characterized by the presence of plaques and patches of 690
hyperkeratosis on the cranial aspect of the rear cannon bones.[65,66] This disorder of keratinization is 691
uncommon and does not appear to have any recognized age, breed, or sex predilection. Clinically, well-circumscribed plaques of tightly adherent crusts and scales with or without alopecia develop over the cranial surface of the rear cannon bones. The lesions are not pruritic.

Diagnosis is usually by clinical examination, and confirmation is by skin biopsy. Differentiating cannon keratosis from dermatophilosis and dermatophytosis is important. Treatment consists of antiseborrheic shampoos. Topical glucocorticoids may be useful. Topical vitamin A cream (tretinoin, Rein-A cream 0.1%, Ortho Pharmaceutical Corp., Raritan, New Jersey) may be beneficial in removing crusts and plaques.

11.9.9.3 Linear Keratosis

Linear keratosis is an uncommon idiopathic disorder of keratinization.[65,66] The disease appears to be heritable, especially in Quarter Horses. Lesions develop between 1 and 5 years of age. One or more painless, nonpruritic unilateral, vertically oriented bands of alopecia and hyperkeratosis develop on the neck or lateral thorax. Lesions vary in size, ranging from 0.25 to 3.5 cm in width and 5 to 70 cm in length. Early lesions may begin as coalescing groups of papules. Lesions are not painful or pruritic.

Diagnosis usually is based on clinical signs alone. Skin biopsy reveals regular, irregular, or papillated epidermal hyperplasia with significant compact orthokeratotic hyperkeratosis.[64] Superficial perivascular dermatitis may or may not be present. If the linear keratosis does not interfere with the function of the horse, no treatment is necessary; surgical excision of small lesions may be curative. Topical vitamin A cream or salicylic cream may be useful in nonsurgical cases. These agents are keratolytic and may decrease the height, width, or thickness or the keratosis, allowing the horse to be used. Owners should not breed affected animals.

11.9.10 IDIOPATHIC CAUSES OF SCALING AND CRUSTING

11.9.10.1 Equine Exfoliative Eosinophilic Dermatitis and Stomatitis

Equine exfoliative eosinophilic dermatitis and stomatitis is an idiopathic disease of horses characterized by ulcerative stomatitis, severe wasting, significant exfoliation, and eosinophil infiltration of the skin.[36,67,68] The disease also is referred to as multisystemic eosinophilic epitheliotrophic disease. No age, sex, or breed predilection exists, but lesions tend to occur more commonly in the winter.

Early lesions begin as scaling, crusting, exudation, and fissuring at the coronary band. Oral ulcers are usually present at this stage. Over several weeks a generalized exfoliative dermatosis develops. Hairs are epilated easily, and alopecia with multifocal areas of ulceration and exudation develops. The horse may be pruritic. Affected horses without ulcerative stomatitis have a good appetite and may even be ravenous, but exhibit rapid, severe weight loss. Some horses have concurrent protein-losing enteropathy or malabsorption syndrome.

Definitive diagnosis is based on the history, physical examination, and skin biopsy. Ruling out pemphigus foliaceus and bullous pemphigoid is important. The chronic wasting nature of the disease and multisystemic signs are key to making a diagnosis. Laboratory features include hypoalbuminemia, hypoproteinemia, impaired small intestinal carbohydrate absorption, and increased activities of γ-glutamyltransferase, serum alkaline phosphatase, and bile duct isoenzymes. A superficial and deep eosinophilic and lymphoplasmacytic dermatitis with irregular epidermal hyperplasia is present.[67,69] Exocytosis of eosinophils and lymphocytes and necrosis of keratinocytes occurs.[36,67,69] Perivascular collagen degeneration, lymphoid nodules, and a lichenoid inflammatory infiltrate may be present. Eosinophilic infiltrates of the pancreas, salivary glands, oral cavity, and gastrointestinal tract are common. Peripheral eosinophilia is usually absent.

Two horses have responded to dexamethasone at 0.2 mg/kg intramuscularly for the first 5 days, followed by prednisolone at 0.5 mg/kg orally every 12 hours for 7 days, and then 1.0 mg/kg every 24 hours for a week, followed by alternate-day therapy.[36,67,69] However, most horses respond poorly to systemic glucocorticoids, and the prognosis is grave. A single horse with this disease showed a partial response to hydroxyurea and dexamethasone therapy.[70]

11.9.10.2 Generalized Granulomatous Dermatitis (Equine Sarcoidosis)

Generalized granulomatous disease is a rare idiopathic skin disease characterized by exfoliation, severe wasting, and granulomatous inflammation of multiple organ systems.[71,72] This disease also has been called equine sarcoidosis because it resembles sarcoidosis of human beings. One should avoid using this term because of possible confusion with sarcoid tumors. The cause of the disease is unknown. The disease may

represent an abnormal host reaction to an infectious agent or allergen[71] or a nonmalignant neoplastic proliferation of cells.

No breed, age, or sex predilection exists for this condition. The skin disease begins as scaling, crusting, and alopecia on the face, limbs, and trunk (Figure 11-19). Clinical signs rapidly become generalized. Occasionally, the disease is focal or multifocal in distribution.[71] Peripheral lymphadenopathy may develop concurrently with weight loss, muscle wasting, anorexia, exercise intolerance, and fever. 691

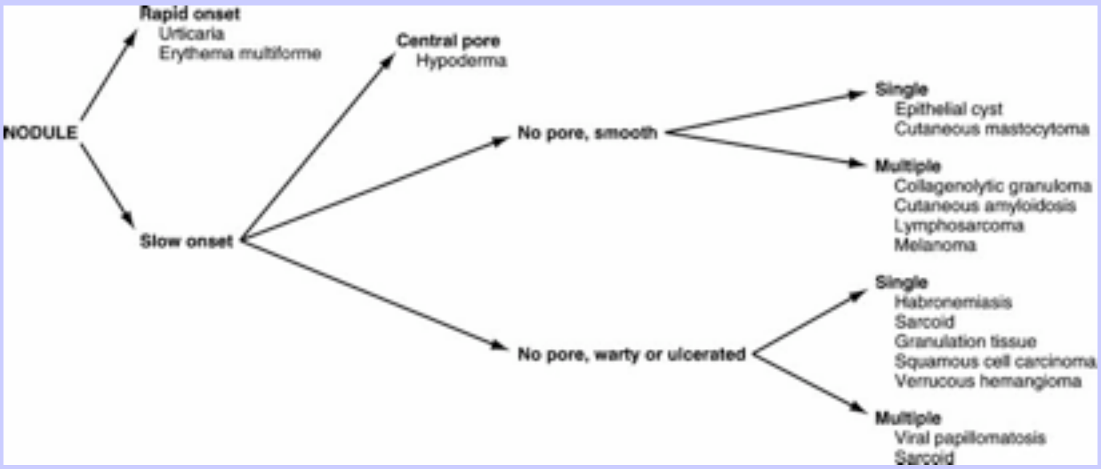
692

Figure 11-19 Horse with generalized granulomatous dermatitis. (Courtesy A.A. Stannard, University of California at Davis.)

Definitive diagnosis is by skin biopsy.[71] Perifollicular and middermal noncaseating granulomatous dermatitis occurs frequently with multinucleated giant cells. Neutrophils, lymphocytes, and plasma cells are present in small numbers. Granulomata are present in the superficial portion of the dermis. Granulomatous infiltrates also occur in other organs, including the lymph nodes, lung, gastrointestinal organs, liver, and spleen. A complete blood count reveals leukocytosis, increased fibrinogen, and hyperglobulinemia. Anemia caused by chronic infection may be present.

The prognosis is grave, and no treatment exists. Horses usually are euthanized within several months. Large doses of prednisolone (2 mg/kg orally every 24 hours) may be beneficial in the early stage of the disease. Occasionally, spontaneous remission may occur.

Figure 11-20 Flowchart for equine nodular dermatitis.



11.10 Diseases Characterized By Papules And Nodules

Many diseases are associated with single or multiple nodules in the skin of horses. Making a definitive diagnosis based on history and clinical signs alone is almost impossible. The most useful and cost-effective diagnostic test is a skin biopsy. Figure 11-20 illustrates a diagnostic algorithm for equine nodular skin disease.

11.10.1 INFECTIOUS CAUSES OF NODULES

11.10.1.1 Bacterial Granulomata (Botryomycosis)

Botryo- is a prefix that means grapelike. Affected horses have clusters of nodular, grapelike lesions. Many species of bacteria have been associated with bacterial granulomata in horses; however, the most commonly isolated organism for equine bacterial granulomata is *Staphylococcus* spp.

Bacterial granulomata begin as traumatic injuries to the skin during which an infectious organism is inoculated into the dermis. A granulomatous reaction develops because the organism is capable of eliciting a response from the host, but the host is only able to contain the infection and not eradicate it. Bacterial granulomata develop in areas of previous trauma and are common on the limbs and scrotum. Poorly circumscribed, firm, draining lesions may or may not be painful. The center of the lesion may be ulcerated. In some cases, variable numbers of white to yellow pieces of particulate matter resembling grains of sand (tissue grains) may be present in the exudate.[73]

692

693

Diagnosis confirmation is by skin biopsy, and identification of the causative organism is by bacterial or fungal culture. Histologic examination of a skin biopsy reveals nodular to diffuse pyogranulomatous inflammation with or without tissue grains. One may observe bacteria.

Surgical excision or radical debulking followed by long-term antibiotic therapy based on culture and sensitivity has been the most successful treatment for bacterial granulomata.[52,73] Organisms may be difficult to isolate from biopsy tissue samples, and submission of large wedges of tissue obtained at the time of surgery

is recommended. If possible, one should obtain tissue to submit for culture from the deepest portion of the lesion to increase the likelihood of isolating an infectious agent and should submit tissue for aerobic, anaerobic, and deep fungal cultures.

11.10.1.2 Corynebacterial Infections

Corynebacterium spp. are gram-positive pleomorphic rods that are associated with two clinical syndromes in horses: abscesses and ulcerative lymphangitis.[47,52,74]

11.10.1.2.1 Abscesses

Corynebacterial abscesses occur frequently in the horse in the western United States. Lesions tend to be seasonal, occurring most commonly during the summer and fall concurrent with peak fly season, especially in dry dusty conditions. The organism is believed to be transmitted by flies, particularly horn flies. For unknown reasons, fly bites are susceptible to infection.

Lesions develop slowly and may be single or multiple. The pectoral and ventral abdominal areas are affected most commonly. These abscesses drain a creamy to caseous material that may be whitish to greenish. Pitting edema, ventral midline dermatitis, depression, fever, and lameness may be present. The course of the disease may be chronic, and recurrent internal abscesses are frequent.

Diagnosis is based on the season and the appearance of the abscess and exudate. Because identifying the organism on cytologic examination of exudate may be difficult, a culture is always recommended.

Treatment is protracted and is complicated by the limited response of the organism to systemic antibiotics. The veterinarian should allow the abscess to mature and then surgically incise and drain it.[52] Systemic antibiotic use before abscess rupture may be followed by recurrence of the abscess on discontinuation of the drug. If drainage cannot be accomplished, large doses of procaine penicillin (50,000 IU/kg intramuscularly every 12 hours) for up to 6 months may be curative.[47,52,73,74] Toxoids and bacterins have not been useful.

11.10.1.2.2 Ulcerative Lymphangitis

Ulcerative lymphangitis is an infection of the cutaneous lymphatics caused most commonly by *Corynebacterium pseudotuberculosis*. Infection is believed to begin by wound contamination. The disease occurs infrequently today.

No age, sex, or breed predilection exists. Lesions usually develop on the hindlimbs, especially at the fetlocks. Hard to fluctuant chains of nodules that abscess, ulcerate, and drain occur most commonly. Old lesions heal within 1 to 2 weeks, but new lesions develop.[48] The affected limb may be swollen and painful, and the horse may be depressed. Regional lymphatics appear corded. In chronic cases, permanent thickening of the tissue surrounding the regional lymphatics is common.

Diagnosis is based on the appearance of the lesion and identification of the organism. Direct smears of the exudate stained with a fast Giemsa or Gram stain and a culture and sensitivity usually confirm the diagnosis.

One must initiate treatment rapidly to prevent permanent debilitation and disfigurement. In early cases, hydrotherapy, exercise, surgical drainage, and large doses of procaine penicillin (20,000 to 80,000 IU/kg intramuscularly every 12 hours) for at least 30 days after clinical normalcy may be curative.[73] Nonsteroidal antiinflammatory drugs may be beneficial. If the area becomes fibrotic and joint motion is restricted, prognosis is poor.

11.10.1.3 Mycetomata

Mycetomata (Table 11-2) are chronic subcutaneous infections characterized by swelling, draining tracts, and tissue granules. Filamentous bacteria or eumycetic fungi (fungi that inhabit the soil or vegetation) may cause mycetomata. The most common fungal organisms that cause mycetomata in horses are *Curvularia geniculata* and *Pseudallescheria boydii*. The most common bacteria isolated from equine mycetomata are *Actinobacillus* spp., *Nocardia* spp., and *Actinomyces* spp. Regardless of causative agent, the organism usually gains entrance to the body through traumatic inoculation. As with other granulomatous reactions, the body is able to recognize the intruder and isolate it but not to eliminate it.

Single or multiple nodules of varying sizes can occur almost anywhere on the body of the horse. The nodules often are pigmented and ulcerated and may discharge tissue grains (small sandlike particles). The tissue grains are believed to be masses of hyphae from the organism. Gross examination of the cut surface often reveals dark-brown pigment or granules scattered in yellow to pink tissue.

Distinguishing clinically among bacterial or fungal mycetomata or any number of other causes of lumps in the skin is impossible. Definitive diagnosis requires an excisional or wedge biopsy of a lesion. Histologic examination shows diffuse to nodular pyogranulomatous to granulomatous inflammation surrounding septate branching hyphae. Tissue grains are often visible microscopically. The hyphae contained in tissue grains or tissue may be pigmented or nonpigmented. Fungi are cultured best from tissue grains and, occasionally, 693

694 exudate. If possible, surgical excision is curative.[52] Antibiotic therapy is usually ineffective, especially for fungal mycetomata.

TABLE 11-2 Fungal Diseases of Horses

DISEASE	COMMON CAUSATIVE AGENTS	CLINICAL SIGNS
SUPERFICIAL INFECTIONS		
Dermatophytosis	*Microsporum* and *Trichophyton* spp.	Circular patches or hair loss, crusting and scaling, urticaria, papules
Piedra	*Piedraia* spp. or *Trichosporon beigelii*	Black or white filamentous nodules on hair shaft
INTERMEDIATE INFECTIONS		
Sporotrichosis	*Sporothrix schenckii*	Papules and nodules occur along lymphatics; nodules may ulcerate, become thickened, and drain a thick brown- to red-colored exudate.
Phaeohyphomycosis (chronic, subcutaneous fungal infection caused by pigmented opportunistic fungi)	*Hormodendrum, Drechslera, Phialophora, Curvularia, Cladosporium*	Single or multiple nodules; lesions may be grossly or microscopically pigmented, nonpruritic, nonpainful, and cool to the touch.
Mycetoma (chronic subcutaneous infection)	Filamentous bacterial organisms and opportunistic fungi	Single or multiple nodular lesions are present; ulcerated, draining tracts are common; mycetomata discharge tissue grains in contrast to phaeohyphomycosis, which does not.

11.10.1.4

Phaeohyphomycosis

Phaeohyphomycosis (see Table 11-2), sometimes referred to as chromomycosis, is a chronic subcutaneous and occasionally systemic infection caused by pigmented opportunistic fungi, such as *Hormodendrum, Drechslera, Phialophora, Curvularia,* and *Cladosporium* species. Many of the organisms that cause fungal mycetomata can cause phaeohyphomycosis. The distinguishing difference is the lack of tissue grains. Pigmented fungi (dematiaceous fungi) causing this disease are soil and vegetative saprophytes that gain entrance into the body via a wound or abrasion. The body is not able to eliminate the organism, which proliferates in tissues. Immunosuppression may be a predisposing factor.

Lesions appear anywhere on the body and may be single or multiple. Some lesions are pigmented deeply on gross examination or pigmentation is only a microscopic feature. Nodules vary in size and are cool, nonpainful, and nonpruritic. Regional granulomatous dermatitis may be present.

Definitive diagnosis is by histologic examination of an excised nodule. Skin biopsy reveals suppurative to granulomatous dermatitis, with pigmented septate hyphae. Observation of pigmented septate hyphae in the skin indicates opportunistic invasion of the tissue. Fungal culture of tissue samples is necessary to identify the organism. An important note is that growth of these organisms is slow, often requiring weeks, and a reference laboratory is able to culture the organism best.

Excision is the only effective treatment but may be impractical when numerous lesions are present. These organisms are not susceptible to commonly used systemic or topical antifungal agents. However, the author has treated an affected dog successfully with itraconazole. The recommended dose is 3 mg/kg orally every 12 hours for 1 month beyond when the skin appears normal (usually 4 to 12 months). Ketoconazole therapy is not recommended in the horse because of poor bioavailability after oral administration. Even when the solution is acidified with hydrochloric acid, bioavailability is approximately 23%.

11.10.1.5 Sporotrichosis

Sporotrichosis (see Table 11-2) is a fungal diseases caused by *Sporothrix schenckii,* a dimorphic aerobic fungus. The organism is a soil and plant saprophyte that lives in decaying vegetation and gains entrance via traumatic inoculation, especially from puncture wounds.

In horses the cutaneous lymphatic form is most common.[75,76] Early lesions begin as papules that may exude a seropurulent material. Nodules are most common on the thigh or proximal foreleg and chest. If the immune system does not eliminate the organism, hard subcutaneous nodules develop along the lymphatics draining the area. The lymphatics become corded and drain thick, brown to red exudate. Regional lymph nodes are not involved. Occasionally, only a solitary nodule develops. Rarely, the disease becomes systemic.

Definitive diagnosis is by demonstration of the organism via cytologic examination of exudate, culture of tissue or exudate, or skin biopsy. The organism appears as a cigar-shaped yeast in macrophages and 694
neutrophils on Giemsa-stained smears. Histologic examination of tissue reveals nodular to diffuse, suppurative 695
to granulomatous dermatitis. Intraepidermal microabscesses may be visible. The yeast rarely is seen in tissue sections. The number of organisms present in the tissue may vary, and repeat cultures are often necessary.

Sodium iodide (20% solution) has been successful for treating sporotrichosis in horses.[76,77] One administers a loading dose of 20 to 40 mg/kg intravenously for 2 to 5 days, followed by once daily oral therapy (20 to 40 mg/kg) until all clinical lesions are gone. One should administer therapy for at least 3 weeks after lesions disappear. One may give sodium iodide orally via syringe or mixed in sweet feed. One may use topical hot packs of 20% sodium iodide on open wounds. Iodism (see the previous discussion) may develop and may require temporary discontinuation of therapy. Iodines cause abortion and should not be used in pregnant mares.[77]

11.10.1.6 Pythiosis (Phycomycosis, Florida Leeches, Gulf Coast Fungus, and Swamp Cancer)

Pythiosis is caused by an aquatic fungus, *Pythium insidiosum,* common in the Gulf Coast region of the United States, South America, and Australia. This organism is a plant parasite that normally lives on aquatic vegetation or organic debris. Damaged animal tissue is chemotactic for the organism, and the fungus probably gains entrance into animal tissue via wounds in prolonged contact with contaminated water.[78]

The disease commonly affects ventral body areas, including legs, abdomen, and chest (Figure 11-21), and also may involve nasal tissue. Wire cuts, puncture wounds, and ventral midline dermatitis caused by horn flies or *Culicoides* gnats are prime locations. Early signs of fungal invasion include single or multiple minute foci of necrosis that progress rapidly into circular, ulcerative, granulomatous masses with serosanguinous discharges. These masses are intensely pruritic and are often hemorrhagic from self-trauma. Thick, sticky material exudes

from the wound. This discharge often contains “kunkers,” hard, gritty, white to yellow masses that develop in tissue tracts and are considered a hallmark of this disease. These granules branch macroscopically, distinguishing them from granules observed in other skin diseases. Kunkers are composed of fungal hyphae, host exudate, and protein. Lameness, regional lymph node involvement, anemia, and hypoproteinemia are common noncutaneous findings. Anemia and hypoproteinemia develop following blood loss and serum exudation from the mass. Occasionally, the disease may become systemic. The disease is not a known zoonosis, but one should wear protective latex gloves when examining patients.

Pythiosis is difficult to differentiate from habronemiasis, exuberant granulation tissue, bacterial granulomata, and invasive squamous cell carcinoma. Definitive diagnosis requires biopsy, culture, and cytologic examination of exudate and kunkers. One should submit tissue specimens and kunkers for histologic examination. Common findings include pyogranulomatous inflammation with large numbers of eosinophils. If hyphae are visible, they are 2.6 to 6.4 μm in diameter, thick-walled, and irregular.[79] Pythiosis can be grown on fungal culture medium and requires incubation in a vegetable extract agar, and a laboratory familiar with appropriate isolation techniques is able best to culture it. One should collect kunkers, wash them in sterile saline, and embed them deeply in the media. Occasionally, one can diagnose the disease by cytologic inspection of the kunkers. One macerates and minces small kunkers with a scalpel, places the material on hydroxide, and stains it with India ink. Hyphae appear as black, broad, thick-walled branching structures.

Figure 11-21 Horse with bilateral pythiosis on the legs.

Prognosis is poor because treatment is difficult. With early diagnosis, surgical excision may be possible. However, relapses are common, and repeated excision may be required. One should monitor surgical sites closely for evidence of recurrence manifesting as focal areas of edema in the granulation tissue with dark hemorrhagic patches 1 to 5 mm in diameter and serosanguinous discharge.

Systemic antifungal drugs are not effective in treating this disease.[78,80] Systemic amphotericin B (Fungizone 695
IV, Bristol-Myers, Squibb, New Brunswick, New Jersey), combined with topical amphotericin B, may be 696
curative in rare, isolated cases. One administers amphotericin B at a dose of 0.3 mg/kg in 5% dextrose intravenously daily until reaching a total dose of 350 mg. One then administers this dose on alternate days until the horse is cured. In addition, one treats lesions topically with gauze dressing soaked in an amphotericin B and DMSO solution (50 mg amphotericin B, 10 ml sterile water, and 10 ml DMSO). One also may inject amphotericin B into the lesions. Amphotericin B is nephrotoxic, and one should monitor serum creatinine and serum urea nitrogen concentrations and hydration daily. Immunotherapy with phenolized, ultrasonicated proportion from fungal culture is reportedly curative if administered early in the course of the disease. In a small number of cases, vaccine administration resulted in a decrease in the size of the lesion. This therapy may be of benefit if used preoperatively to enhance complete removal of the infected tissue. Unfortunately, the vaccine is not commercially available. Because of the cost of medical or surgical therapy, the risks of treatment, and the high probability that excision is incomplete, owners often elect euthanasia.

11.10.2 PARASITIC CAUSES OF NODULES

A variety of parasites may infest equine skin and cause cutaneous nodules. Some of the more common causes of parasitic nodules in the horse are warbles, cutaneous habronemiasis, and ticks. The latter two have been discussed previously and are not covered in this section.

Warbles occasionally occur in horses and are caused by a larval stage of *Hypoderma bovis* and *Hypoderma lineatum*. In horses, larvae do not usually complete their life cycle.[23] Horses that develop infestation usually are pastured or housed with cattle. Adult flies lay eggs on the hairs, and larvae migrate toward the skin surface and eventually penetrate the skin. Once in the body of the host, the larvae migrate to reach the subcutaneous tissues of the neck and trunk. A swelling develops at the site of the larvae, which eventually becomes perforated as a breathing pore is formed. Nodules are visible most commonly over the withers, and almost all develop a breathing pore. The nodules are often painful. Spontaneous rupture may cause anaphylaxis.[23] Occasionally, aberrant migration causes neurologic signs.

The presence of dorsal swelling or a nodule with a breathing pore is diagnostic. The major differential consideration is collagenolytic granuloma; however, these nodules lack a breathing pore. One treats hypodermiasis by gently enlarging the breathing pore surgically and removing the grub, removing the entire nodule surgically, or allowing the grub to fall out spontaneously. In areas of high occurrence, one may use pour-on insecticides as a preventative. One should treat horses at the same time of year as one treats affected cattle in the area.

Figure 11-22 Urticaria in a horse following administration of penicillin.

11.10.3 URTICARIA

Urticaria is a nodular skin disease of horses characterized by wheals, edema, and often pruritus (Figure 11-22) and most commonly is caused by a type I hypersensitivity reaction. However, urticaria also may result from nonimmunologic factors such as pressure, sunlight, heat, exercise, stress, and drugs. Prerace stress, insect or arthropod bites, bacterial infections, topical parasiticides, systemic drugs (penicillin, phenylbutazone, aspirin, guaifenesin, phenothiazine, quinidine, streptomycin, oxytetracyline), feedstuffs, soaps, leather conditioners, vaccines, snake bites, inhalants, and plants can cause urticaria in horses. In the author's experience, urticaria is a common manifestation of insect hypersensitivity and atopy. Mosquito swarmings commonly result in urticaria.

No age, sex, or breed predilection exists for urticaria. Lesions may develop rapidly or slowly and may be localized or generalized. Lesions are raised, cool to the touch, pit when depressed, and may or may not exude serum or blood. Pruritus varies. In rare instances, lesions may coalesce to form bizarre patterns.

Although urticaria is usually recognizable, its cause can be difficult to identify. The cause of an acute urticaria episode (less than 6 weeks in duration) is much more likely to be identified than the cause of a chronic episode (greater than 6 weeks in duration). A detailed history is critical. Important questions to answer are these:

1. Is this a corticosteroid-responsive urticaria? This suggests an allergic cause such as atopy, insect hypersensitivity, or food allergy.
2. Does the development of the lesion correlate with the administration of systemic drugs or the application of topical medications? This would suggest a drug reaction.

3. Does the application of fly repellent aggravate or alleviate the urticaria? Worsening of the urticaria suggests an allergic contact reaction, whereas alleviation suggests an insect hypersensitivity. 696 697

4. Do the lesions resolve with stabling the horse for 24 to 48 hours or moving to a new environment? If so, this would suggest an environmental cause of the urticaria (molds, inhaled dust from bedding, hay, feedstuffs, feathers from roosting birds).

5. Do lesions improve if the horse is moved off pasture? A positive answer would suggest plant antigen as a cause of the urticaria.

6. Do the lesions improve if the feed is changed? Improvement in clinical signs suggests an ingested allergen or inhaled allergen from feedstuffs.

In cases in which lesions are bizarre in appearance, chronic, or exudative, one should perform a skin biopsy to rule out other causes of nodular disease. Typical histologic findings for urticaria include vasodilation, edema in the dermis, and mild to moderate eosinophilic perivascular inflammation. Complete blood cell counts and serum chemistry profiles are rarely useful. Before beginning expensive or involved diagnostic testing, one should be sure to rule out the possibility of allergic reactions to shampoos, tack cleaners, soaps, etc. All horses with chronic urticaria should undergo a food trial, be moved to a new environment for 5 to 7 days, and undergo a program of insect control before being referred for intradermal skin testing. Intradermal skin testing is the best method for identifying the cause of allergic inhalant dermatitis. Horses should not receive antihistamines or tranquilizers for 1 week or corticosteroids for 4 weeks before intradermal skin testing.

Treatment aims at eliminating the underlying cause, if possible. Hydroxyzine at 200 to 400 mg orally every 12 hours is effective in eliminating urticarial swellings in most horses with acute or chronic urticaria.[34] Transient sedation of several days may occur with this drug. If the horse is nonresponsive to hydroxyzine, prednisone at 1 mg/kg orally, intravenously, or intramuscularly may be beneficial on a short-term (less than 1 week) basis.

11.10.4 IDIOPATHIC INFLAMMATORY CAUSES OF NODULES

11.10.4.1 Eosinophilic Collagenolytic Granuloma (Nodular Collagenolytic Granuloma and Nodular Necrobiosis)

Eosinophilic granulomata are a frequent cause of nodules in the skin of horses. The exact cause of these lesions is unknown, but they may result from a hypersensitivity reaction to insect bites.[51] Lesions, however, have been reported to develop spontaneously or as a result of trauma, suggesting multiple causes.[81] Regional variability in the occurrence of lesions has been noted.

These lesions have no sex, breed, or age predilection but occur most commonly in warmer months. They may be single or multiple and vary greatly in size (0.5 to 10 cm in diameter). The nodules may occur anywhere on the body but are most common on the neck, withers, and dorsal trunk (Figure 11-23). Individual lesions are rounded, well circumscribed, firm, haired, nonpainful, and nonpruritic. Owners of horses with seasonal problems have reported that early lesions are often soft and fluctuant and develop into firm masses over weeks to months. If lesions are under the saddle, the horse may exhibit pain.

Definitive diagnosis is by skin biopsy. Histologic examination of tissue reveals multifocal areas of collagen degeneration surrounded by granulomatous eosinophilic inflammation. Chronic lesions may have significant dystrophic mineralization.[64]

Solitary lesions that do not cause the horse discomfort require no treatment. Problem lesions respond to excision or sublesional injections of triamcinolone acetonide (3 to 5 mg per lesion) or methylprednisolone acetate (5 to 10 mg per lesion).[51] One should inject no more than 20 mg per horse of triamcinolone acetonide because of the danger of laminitis. Horses with multiple lesions may be treated with prednisolone orally at 1 697
mg/kg once daily for 2 to 3 weeks. After lesions have resolved, one should taper the dose of prednisolone and 698
discontinue it over a 5- to 10-day period. Horses with seasonal recurrences in which insect hypersensitivity is involved and documented via intradermal skin testing might benefit from hyposensitization to insects.

Figure 11-23 Horse with multiple eosinophilic granulomata.

11.10.4.2 Equine Axillary Nodular Necrosis

Equine axillary nodular necrosis is a rare idiopathic skin disease of horses. The disease is similar to equine eosinophilic granuloma with collagen degeneration, except that the lesions are localized to the axillary region. [27]

The condition has no known age, sex, or breed predilection. Clinically, single or multiple nodules develop unilaterally in the axillae. The nodules are painless, nonpruritic, haired, well-circumscribed firm masses that vary in size from 0.5 to 4.0 cm or greater in diameter. Multiple lesions tend to be arranged in a row.

Skin biopsy is diagnostic. Biopsy findings include pyogranulomatous, eosinophilic dermatitis with foci of coagulation necrosis. Collagen degeneration is not a common finding.

Treatment is the same as for equine eosinophilic granuloma. Corticosteroids often do not work well, and surgical excision may be necessary. Lesions tend to recur.

11.10.4.3 Equine Unilateral Papular Dermatosis

Equine unilateral papular dermatosis is a rare idiopathic skin disorder of horses.[82] This disease has been seen in several breeds of horses but may be more common in Quarter Horses. Lesions develop in the warm months and are characterized by the unilateral development of multiple (30 to 300) papules and nodules on the trunk (Figure 11-24). Lesions are firm, well circumscribed, nonpainful, and nonpruritic.

Diagnosis is by skin biopsy. Histologic examination of tissue reveals eosinophilic folliculitis and furunculosis. Spontaneous remission may occur; otherwise, prednisolone at 1 mg/kg orally once daily for 2 to 3 weeks is recommended until nodules resolve. Relapses may occur.

11.10.5 NEOPLASTIC CAUSES OF NODULES

Reviewing all of the neoplastic skin conditions of horses is beyond the scope of this chapter. Only the skin tumors of horses that commonly masquerade as nodules are discussed: sarcoids, melanomas, mast cell tumors, and cutaneous lymphoma. One can diagnose some cutaneous neoplasms via exfoliative cytologic examination, but biopsy is the diagnostic test of choice.

11.10.5.1 Sarcoids

Sarcoids are the most common skin neoplasms in horses, accounting for up to one third of all reported tumors in horses. Sarcoids are locally invasive fibroblastic neoplasms.[83–89]

Figure 11-24 Horse with unilateral papular dermatitis. (Courtesy V. Fadock, University of Florida.)

The cause of equine sarcoids is controversial; currently the papovavirus is believed to be involved in development of lesions.[82,84,85] Polymerase chain reaction nucleotide sequences strongly suggest that equine sarcoids are caused by bovine papillomavirus types 1 and 2.[86] Evidence for this includes the clinical observations that lesions often develop in areas of previous trauma, lesions may spread to other areas on the same horse or to other horses, epizootics of equine sarcoid have been described, and autotransmission is possible under experimental conditions. Equine sarcoids were produced in donkeys inoculated experimentally with bovine papillomavirus. A predisposition or susceptibility also appears to play a part in the pathogenesis. Equine sarcoids occur with increased incidence in certain families, and a genetic link with specific major histocompatibility genes (W13 MHC class II antigen) has been demonstrated. Exposure to the virus and genetic susceptibility are probably required for a horse to develop sarcoids.

No sex or breed predilection exists, but greater than 70% of sarcoids develop in horses less than 4 years of age. They may arise spontaneously or at a site of previous trauma and may occur anywhere on the body. Sarcoids have a predilection for the head, ears, and limbs. One third of affected horses have multiple lesions.

Equine sarcoids may be classified as (1) nodular sarcoids, (2) fibroblastic sarcoids (Figure 11-25), (3) verrucous sarcoids, (4) occult or flat sarcoids (Figure 11-26), (5) malevolent sarcoids, and (6) mixed sarcoids. Each type of sarcoid differs clinically in its morphologic appearance and lesion location.[89] Nodular sarcoids are firm, raised, circular nodules that are 5 to 20 mm in diameter and tend to occur on the sheath/groin areas and the eyelids. Fibroblastic sarcoids resemble proud flesh (proliferative, fleshy, and ulcerated lesion) and usually are located around the groin, lower limbs, coronet, and eyelid. Verrucous sarcoids are warty and tend to occur on the face, body, and sheath/groin areas. Occult sarcoids normally appear as flat, circular, hyperkeratotic areas. Occult sarcoids also may appear as one or more small nodules 2 to 5 mm in diameter. The typical lesion location for occult sarcoids is the neck, mouth, eyes, and the medial aspects of the forearm and thigh. Malevolent sarcoids are locally invasive tumors with multiple nodules and a fibroblastic character. Some malevolent sarcoids infiltrate lymphatics and produce a cordlike appearance. Although local lymph nodes are enlarged, no evidence of saroid tumor has been detected within the lymph nodes themselves. Mixed sarcoids consist of sarcoid lesions that appear as a confluence of several different types of sarcoids. Mixed sarcoids contain verrucous/occult type tissue along with fibroblastic/nodular-appearing tissue. This type of sarcoid is more common in long-standing sarcoid lesions or lesions that have experienced minor trauma.

Figure 11-25 Fibroblastic (proliferative) sarcoid.

Figure 11-26 Flat sarcoid.

A skin biopsy is the only way to diagnose an equine sarcoid definitively. Flat or small verrucous forms may become more aggressive after a biopsy. For this reason, some veterinarians are reluctant to take a biopsy sample of these lesions.

The histologic pattern observed with equine sarcoids is a fibroblastic proliferation of cells that form whorls or interlacing bundles.[64] The usual overall orientation of this proliferation is perpendicular to the basement membrane, but exceptions exist. The epidermis, when present, is hyperplastic with characteristic elongated rete ridges, but normal or even atrophic epidermis with significant hyperkeratosis can occur (flat sarcoids).

Several different treatments are described for managing equine sarcoids.[77,87–89] Previous experience suggests that the best treatment for occult and verrucous sarcoids is benign neglect. These types of sarcoids become more aggressive after biopsies have been performed. For fibroblastic sarcoids, the treatment of choice is cryotherapy along with surgical debulking of the tumor. The inclusion of cryotherapy in the treatment regimen is associated with a lower rate of recurrence than with surgery alone (30% to 40% recurrence rate for cryosurgery versus 50% to 64% recurrence rate with traditional surgery). Adverse effects associated with cryosurgery include swelling, hyperemia, hemorrhage, necrosis, and local edema after treatment. Average healing time after cryosurgery is 2.4 months with a range of 1 to 3.5 months. Cryotherapy usually destroys hair follicles in the treated area, and hair regrowth is white. If cortical bone is accidentally freezes, the strength of the bone may decrease by 70%. For lesions around the eyes, recommended treatment is surgical debulking of the tumor followed by injections with bacille Calmette-Guérin (BCG) vaccine or mycobacterial cell wall products. BCG is thought to work by stimulating the immune response of the host to sarcoid cells. 699 700
Mycobacterial antigens are thought to stimulate host lymphocytes and also may stimulate an increase in natural killer cells. One injects the tumor with BCG every 2 to 3 weeks for four treatments. One should

pretreat horses with flunixin meglumine and prednisolone 30 minutes before using BCG vaccine to help reduce the risk of anaphylaxis.

Local radiation therapy using a variety of implants also has been recommended for treating equine sarcoids. This form of treatment is limited to smaller lesions because radiation does not effectively penetrate deeper skin lesions. Relapse rates with this form of therapy vary from 0% to 50%. Some disadvantages of radiation therapy are that the horse must be kept in a radiation-approved area and cost may be significant if the tumor is large.

Cisplatin (Platinol, Bristol Myers Squibb, Princeton, New Jersey) in oil recently has been described as a treatment for horses with sarcoids. This treatment may be up to 100% effective, but requires multiple intralesional injections. Emulsions are made of equal volumes of an aqueous solution of 1 mg cisplatin per milliliter of sesame or almond oil. A dose of 1 mg cisplatin per cubic centimeter of tumor is suggested. With denser sarcoid tumors, injecting cisplatin solution into the tumor may be difficult. Precautions recommended when using cisplatin include wearing gloves and protective clothing. One should place all material in a biohazard container after use and should use a Luer-Lok syringe and extension set to help minimize potential human exposure. Local skin reactions may occur when cisplatin contacts the skin and mucous membranes and require thoroughly washing the area with soap and water. One should not use cisplatin in patients with renal impairment or in breeding animals. Cisplatin is associated with teratogenic and embryotoxic reactions in mice and azoospermia and impaired spermatogenesis in human beings.

Another recently described therapy for equine sarcoids is a topical treatment known as Xxterra (Larson Laboratories, Fort Collins, Colorado).[82] This product contains a caustic substance and an extract of the bloodroot plant. Native Americans have used the bloodroot plant to treat a variety of conditions including warts. This product is thought to work by changing the antigenicity of the sarcoids so that the body recognizes these cells as foreign and produces antibodies against them. One applies Xxterra (while wearing gloves) to the sarcoid lesion and places a bandage over it for 4 days. If the sarcoid has not sloughed by 4 days, one repeats the treatment. If one cannot bandage the area with the sarcoid, then one should apply the product to the sarcoid daily for 4 days or until sloughing occurs. Interestingly, when this product was applied to normal skin nothing happened, but when the product was applied to a sarcoid, the skin became inflamed and the sarcoid sloughed. An exception to this is pigmented skin. If freckles are present on the skin, Xxterra may react with them. Horses with mixed coat colors or Paint Horses have not had problems with this tissue reaction. Application of Xxterra to the ears may result in crinkling of the ears. If this would be an unsatisfactory side effect for the owner, one should use a different treatment. In addition, the veterinarian should warn owners that the treated area may ooze a purulent material and become malodorous. This often occurs before the tissue sloughs.

Other therapies for equine sarcoids that have been used with success are limited in their use because of expense and availability. Examples of such treatments include radiofrequency-induced hyperthermia, carbon dioxide laser surgery, and immunotherapy using a tumor vaccine. With time, these therapeutic options may become more readily available and accepted.

Regardless of the form of therapy chosen, the client needs to be aware that sarcoid tumors tend to recur. Verrucous or flat tumors are best left untreated.

11.10.5.2 Melanomas

Melanomas may arise from dermal melanocytes or melanoblasts and may be benign or malignant. These tumors occur most commonly in older horses of Arabian and Percheron breeding. The relationship between

development of melanomas and gray coat color is recognized widely.[90] Melanomas appear to occur exclusively in horses that are gray or become dapple-gray with age. Up to 80% of gray horses more than 15 years of age are estimated to have melanomas.[91]

Lesions may be solitary or multiple and occur most commonly on the perineum or ventral surface of the tail. Tumors are usually firm and nodular and may be hairless and ulcerated. They are almost always black. Vitiligo may precede the development of the lesions.[90] Three growth patterns have been described: (1) slow growth without metastasis, (2) slow growth with sudden metastasis, and (3) rapid growth and malignancy from the onset.

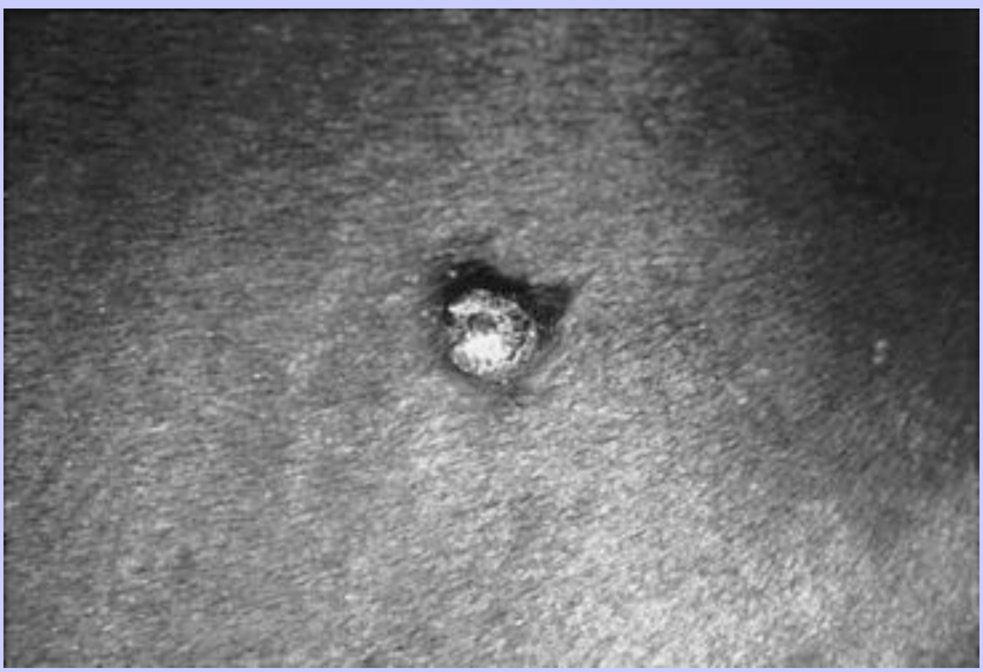
Diagnosis usually is based on clinical signs. Biopsy usually is not needed to confirm the diagnosis unless the lesion is bizarre in appearance.

No treatment is needed unless the melanoma interferes with function. Cimetidine (Tagamet) at 2.5 mg/kg every 8 hours has been reported to cause partial to complete regression of some melanomas. The number and size of the melanomas decrease by 50% to 90% in horses treated for 3 months. After tumors have regressed, daily maintenance therapy at 1.6 mg/kg orally once daily is recommended.[92]

11.10.5.3 Mastocytoma (Mast Cell Tumor)

Mast cell tumors are uncommon in horses. Equine mast cell tumors are 5 times more common in males than 700
females. Arabian Horses appear to be predisposed to developing mast cell tumors. The breed that is least 701
predisposed to developing mast cell tumors is the Thoroughbred.[27,51] No age predilection exists for equine mast cell tumors.

Figure 11-27 Hyperplastic mast cell tumor in a horse.



Two distinct types of mast cell tumors in horses are a hyperplastic type and a neoplastic type. Most equine mast cell tumors are hyperplastic. Clinically, two forms of equine mast cell tumors exist.[51] The most common form is a single cutaneous nodule, often located on the head (Figure 11-27). Nodules range in size from 2 to 20 cm in diameter. The surface of the nodules may be normal, hairless, or ulcerated. Alternatively, mast cell tumors may present as a diffuse swelling on a lower extremity, usually below the carpus or hock. The swelling is firm, and the overlying skin is normal in appearance. Radiographs of the limb commonly show multifocal areas of soft tissue mineralization.[64]

Diagnosis is by biopsy. Diffuse to nodular proliferations of mast cells occur in the dermis. Tumor cells may be well differentiated or more atypical. Tissue eosinophilia, collagen degeneration, and dystrophic mineralization occur commonly in horses.

One may treat solitary tumors by excision, with sublesional triamcinolone acetonide (5 to 10 mg per lesion), or with cryosurgery. Spontaneous remission may occur following incomplete excision or in young horses. Metastasis has not been reported.[27]

11.10.5.4 Cutaneous Lymphoma

Cutaneous lymphoma is rare in horses.[81,93] No age, sex, or breed predilection exists for this tumor. Most affected animals have another concurrent systemic disease, and weight loss, anorexia, anemia, and lymphadenopathy are commonly present. Lesions develop slowly or rapidly. They may occur anywhere on the body, but the trunk and neck are affected most commonly. Individual lesions may be firm or fluctuant, resembling urticaria. The overlying skin is usually normal. Involvement of internal organs may occur.

Definitive diagnosis is by histologic examination of a skin biopsy. One should submit several representative tissue samples for examination. Histologically, lymphosarcoma is characterized by diffuse dermal and subcutaneous infiltration of malignant lymphocytes.[94]

If the owners want to pursue treatment, several options are available. Prednisolone at 1 mg/kg orally once daily for 7 days and then every other day has been used successfully. In addition, PEG-L-asparginase at 10,000 IU/m^2 once weekly may be beneficial, although expensive. Recently, low-dose cyclophosphamide and immunization with vaccinia virus-infected autologous tumor cells was successful in inducing a 19-month remission in a 13-year old horse; however, this therapy is experimental.[95]

11.10.5.5 Pseudolymphoma

Pseudolymphomata are common in horses compared with lymphomata.[51] Differentiating the two diseases is important because the prognosis for pseudolymphoma is excellent.

Pseudolymphomata are nodular to papular lesions that develop in the skin as a result of chronic antigenic stimulation. The most common antigenic stimuli are believed to be insect bites and drug reactions. Lesions occur most commonly in late summer and fall and are usually solitary but may be multiple.[51,93] Pseudolymphomata usually occur on the head and trunk. Individual lesions are firm, raised, and haired.

Definitive diagnosis is by a skin biopsy. Histologic examination of tissue shows dense dermal and subcutaneous infiltration of lymphocytes, histiocytes, plasma cells, and eosinophils. Lymphoid nodules and

eosinophils are present and are an important aid in the differentiation of pseudolymphoma from lymphoma.[64,93]

Pseudolymphomata often spontaneously regress but may be excised surgically or injected sublesionally with triamcinolone acetonide at 3 to 5 mg per lesion, not to exceed a total dose of 15 to 20 mg.[93]

11.10.6 CONGENTIAL CAUSES OF NODULES

11.10.6.1 Dermoid Cysts

A dermoid cyst is a tumor of developmental origin consisting of a wall of fibrous tissue lined with stratified epithelium containing hair follicles, sweat glands, sebaceous glands, nerves, or any combination of these. Dermoid cysts may be congenital or hereditary, have been reported in horses 6 months to 9 years of age, and are common in Thoroughbreds.[96] They occur frequently on the dorsal midline between the rump and withers. The cysts appear as soft, fluctuant swellings with normal overlying skin. Diagnosis is by histologic examination after excision. 701

702

11.10.6.2 Atheroma (False Nostril Cyst)

An atheroma is a cyst in the false nostril. These lesions are believed to develop from hair follicle retention cysts or from displaced germ material.[92] Atheromata are present at birth, usually are unilateral, and enlarge with time. They usually are not noticeable until they enlarge to greater than 2 cm. The tumor is firm on palpation but is rarely painful.

Diagnosis is by clinical signs. Treatment is not necessary unless the tumor compromises breathing or the owner is disturbed by the lesion. Surgical excision is the treatment of choice, but one must take care to remove the entire cyst, lest recurrence or chronic drainage occur.

11.11 Disorders Of Pigmentation

Skin and hair color depend on melanin production in the skin. Melanocytes produce pigment at the dermal-epidermal junction and in the outer root sheath of the hair follicle. The ratio is one melanocyte for every 10 to 20 keratinocytes. Melanin pigments have a wide range of colors including black-brown eumelanins, yellow-red pheomelanins, and a range of intermediate pigments. Special tyrosinase-rich organelles called melanosomes, which are found in the cytoplasm of melanocytes, produce melanin pigment. Tyrosine is converted to dopa, which is oxidized to dopaquinone. The copper-containing enzyme tyrosinase catalyzes both reactions. Subsequent intermediate products polymerize, eventually forming melanin. Melanocytes secrete or inject melanosomes into adjacent keratinocytes. Production of melanin is controlled by genetics, hormones, local keratinocytes, and Langerhan's cells. Ultraviolet light, inflammation, by-products of the arachidonic acid cycle, androgens, estrogen, glucocorticoids, and thyroid hormone also may influence pigmentation.[93]

The number, size, type, and distribution of melano-somes determines skin and hair color. Melanosomes are responsible for coat color, photoprotection, free radical scavenging, and heat conservation.

11.11.1 CAUSES OF HYPERPIGMENTATION

Hyperpigmentation is almost always an acquired change. The skin and hair may become hyperpigmented. The usual cause of localized or patchy hyperpigmentation is chronic inflammation or irritation. Macular patches of noninflammatory hyperpigmentation, called lentigo, can occur in horses. Lentigo occurs most frequently at mucocutaneous junctions. The most important differential diagnosis for lentigo is cutaneous melanoma. A skin biopsy of the affected area is the most useful diagnostic test. Generalized hyperpigmentation of the coat or skin has not been reported; however, if observed, the condition may suggest an underlying hormonal disorder.

11.11.2 CAUSES OF HYPOPIGMENTATION

Hypopigmentation is a decrease in normal melanin pigmentation. Depigmentation specifically refers to a loss of preexisting melanin. *Leukoderma* and *leukotrichia* are clinical terms used to describe the loss of color in skin and hair, respectively. Amelanosis is a total lack of melanin.

11.11.2.1 Albinism and Lethal White Foal Disease

Albinism is rare in horses and is transmitted by an autosomal dominant gene. Affected animals have white skin and hair, hypopigmented irides, and photophobia. Lethal white foal disease has two forms. One form is caused by an autosomal dominant gene characterized by early embryonic death in the homozygous state. The second form results from breeding of two overo Paint Horses and is an autosomal recessive disorder. Affected foals are characterized by a white hair coat and congenital ileocolonic aganglionosis.

11.11.2.2 Leukoderma

Leukoderma develops in areas of previous trauma or inflammation and may be temporary or permanent. Affected areas appear normal but depigmented. Leukoderma occurs commonly in horses with onchocerciasis, lupus erythematosus, pressure sores, ventral midline dermatitis, viral skin diseases, freezing, burns, or sun damage (Figure 11-28). Leukoderma can result from the contact of skin with chemicals that inhibit or interfere with melanogenesis, such as phenol and rubber products containing monobenzyl ether or hydroquinone.

Diagnosis usually is by clinical signs, but elliptic biopsy of the junction of the pigmented and nonpigmented area confirms the diagnosis. Leukoderma causes no discomfort to the horse, but may be a source of great agitation to the owner. No treatment is known.

Figure 11-28 Idiopathic leukoderma in a horse.

702

703

Figure 11-29 Horse with Arabian fading syndrome. Depigmented areas on the face are notable.

11.11.2.3 Vitiligo of Arabian Horses (Arabian Fading Syndrome and Pinky Syndrome)

The term *vitiligo* refers to an idiopathic acquired depigmentation. Leukoderma develops in areas with no known history of previous trauma. Vitiligo can occur in any age, sex, or breed of horse but is most common in the Arabian (Figure 11-29).[51] Vitiligo appears to be more common in pregnant or postpartum mares, suggesting a hormonal or stress influence. In addition, the condition may be hereditary.[96]

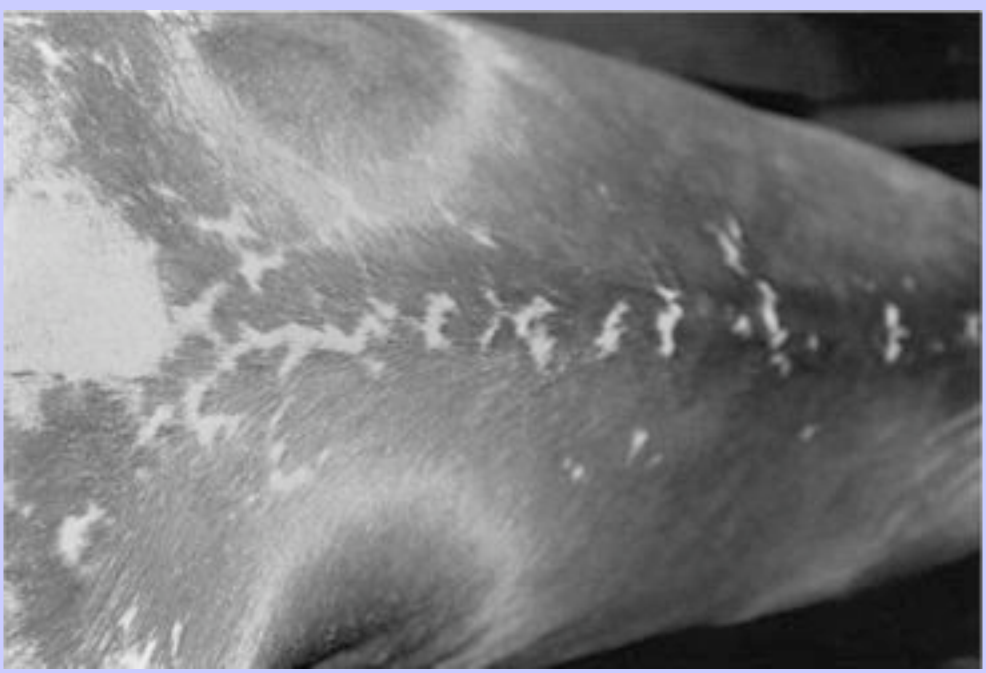
With vitiligo, annular areas of depigmentation develop symmetrically on the muzzle, face, lips and periocular areas. Depigmentation also can occur at the mucocutaneous junctions of the genital and anal area. Areas of depigmentation vary from 1 mm to 2 to 3 cm in size, and spots may become confluent at the mucocutaneous junctions. Depigmentation may wax and wane, and rarely the skin repigments completely within 1 to 2 years.

History, physical examination, and skin biopsy are diagnostic. Skin biopsy shows complete absence of epidermal melanin and lack of an inflammatory infiltrate. Success of treatment with topical glucocorticoids and vitamin-mineral supplement (i.e., cooper) is unpredictable. One should consider the condition untreatable, and owners should not breed affected animals because the condition is heritable and is considered a flaw. More practically, these areas are prone to sunburn and may predispose the horse to squamous cell carcinoma.

11.11.2.4 Leukotrichia

Leukotrichia is an acquired loss of pigment in hairs that occurs most commonly in areas of previous trauma or inflammation. Leukotrichia also may occur at the site of previous injections of epinephrine with or without lidocaine.

Figure 11-30 Reticulated leukotrichia in a Quarter Horse.



Reticulated leukotrichia is an inherited disorder of Quarter Horses, Thoroughbreds, and Standardbreds[51,96,97] (Figure 11-30). The condition has no sex predilection. Affected horses begin to show clinical signs as yearlings. Linear crusts in a netlike to crosshatched design develop over the dorsum from the withers to the tailhead region. Crusts are shed and after the temporary alopecia resolves, new hair growth is white. The underlying skin is normal, and leukotrichia is permanent. Leukotrichia causes no discomfort to the horse or interference with training or use of the animal. No therapy is available, and owners should not breed affected animals because leukotrichia is considered a breed flaw.

Spotted leukotrichia is a similar condition observed most commonly in Arabian Horses.[51,96,97] Permanent spots of leukotrichia develop over the hindquarters and trunk. Occasionally, lesions resolve spontaneously. No treatment is known, and owners should not breed affected animals because the condition is a breed flaw.

Hyperesthetic leukotrichia is a rare disease reported only in California.[98] Single or multiple crusts that are intensely painful characterize this disorder. Lesions develop on the dorsal midline from the withers to the tailhead. Within a few weeks, white hairs develop in the areas of crusting. The intense pain and crusting may last weeks to months. Eventually, lesions subside, but leukotrichia is permanent. Skin biopsy shows significant subepidermal and intraepidermal edema. No treatment is known, and large doses of glucocorticoids have not been of value.

11.11.2.5 Discoid Lupus Erythematosus

Discoid lupus erythematosus is a rare skin disease in horses that is believed to be a variant of systemic lupus 703
erythematosus. Affected horses develop areas of patchy erythema, crusting alopecia, and scaling on the face, 704
ears, and neck.[36] Leukoderma and leukotrichia may be present.

The diagnostic test of choice is a skin biopsy. The skin biopsy reveals an interface dermatitis (hydropic or lichenoid or both). Focal hydropic degeneration of basal epidermal cells, pigmentary incontinence (pigment granules in the dermis or in dermal macrophages), and focal thickening of the basement membrane are important histologic features. Direct immunofluorescence testing may show a linear deposition of immunoglobulins at the basement membrane zone. This test is not reliable and is not recommended as a substitute for a routine histopathologic study.

One treats discoid lupus erythematosus on an individual basis. Ideally, the owner should stable the horse during the hours of strong sunlight because sunlight aggravates the disease.[36] Topical sunscreens and topical glucocorticoids, for example, 0.1% betamethasone 17-valerate may be beneficial. Severe or refractory cases of discoid lupus erythematosus may require immunosuppressive doses of oral prednisolone (see the section on pemphigus foliaceus).

11.12 Disorders Of Collagen Formation

Hyperelastosis cutis is a defect in collagen that occurs primarily in cutting horse strains of Quarter Horses and horses of Quarter Horse lineage (Paints and Appaloosas).[99–102] A similar condition has been described in an Arabian cross-breed. Male and female horses are affected equally. Hyperelastosis cutis is thought to be an autosomal recessive trait. Foals are born with hyperelastosis cutis but the condition may take months to years before becoming clinically apparent to the owner. Clinical signs include loose skin that is hyperextensible, hyperfragile, and easily torn and that exhibits impaired healing (Figures 11-31 and 11-32). Lesions may be solitary

or multiple, and the most common lesion location is the dorsal body surface. Affected horses rarely if ever exhibit hypermobility of the joints. Occassionally, owners complain that the horse develops hematomas and subcutaneous abscesses.

Figure 11-31 Horse with severe hyperelastosis cutis.

Figure 11-32 Horse with mild hyperelastosis cutis.

Diagnosis is based on clinical signs, physical examination, and skin biopies. The most common histologic findings are an absent or greatly diminished deep dermal collagen layer. Other changes that may occur are thinning of the dermis and thinning, fragmented, and disordered collagen fibers. Zonal dermal seperation is a distinctive histopathologic lesion associated with hyperelastosis cutis in the Quarter Horse.[102]

No treatment for hyperelastosis cutis is available. Owners should attempt to minimize trauma to affected horses and promptly treat secondary infections. Most affected horses are euthanized because their fragile skin impairs their usefulness. Owners should remove sires and dams of affected horses from the breeding stock.

11.13 Hair Abnormalities

Horses have simple hair follicles, which are accompanied by a sebaceous and sweat gland and an arrector pili muscle. Photoperiods and ambient temperature predominantly govern the hair cycle. Nutrition, hormone, genetics, and general well-being also may influence hair growth. Hair replacement in the horse occurs in a random pattern (mosaic) with the exception of the coarse permanent hair of the mane, tail, and fetlock.

11.13.1 CHEMICAL AND PLANT CAUSES OF COAT ABNORMALITIES

11.13.1.1 Selenium Toxicosis

Selenium is a trace mineral found in high concentrations in the Great Plains and Rocky Mountain areas of the
United States. Toxicosis occurs when high levels of selenium in the soil are concentrated in selenium- 704
concentrating plants. Interestingly, many of these plants grow selectively in selenium-rich soil and can contain 705
up to several thousand parts per million of selenium. Selenium toxicosis also may occur when water contains 0.1 to 0.2 ppm selenium or feed contains greater than 5 ppm.[60] The exact mechanism of action is unknown, but selenium is believed to interfere with oxidative enzyme systems that possess sulfur-containing amino acids by displacing the sulfur groups. Selenium is substituted for sulfur in sulfur-containing amino acids. Keratinization of the hoof and hair especially are affected by the defective amino acids.

Selenium toxicosis occurs in any age, breed, or sex of animal but is most common in horses on pasture.[103] Early lesions begin as lameness and soreness of the coronary band and feet. The hindfeet usually are affected first. The coronary band and hoof develop cracks and separation and eventually the hoof may slough. The hair coat becomes rough, and generalized epilation of the long hairs of the mane and tail occurs. Generalized alopecia may be visible.

Definitive diagnosis is by history, clinical signs, and tissue analysis for selenium levels. Selenium in excess of 1 to 4 ppm from blood, 11 to 45 ppm for hair, and 8 to 20 ppm for hoof indicates chronic toxicity. Identifying and removing the exogenous source of selenium is critical. Treatment of individual animals is frustrating because of the prolonged recovery period. Chronically affected animals have a 50% chance of recovery. A high-protein diet rich in sulfa-containing amino acids and 2 to 3 mg orally per day of DL-methionine may be beneficial. Naphthalene orally at 4 to 5 g per adult horse also may be of benefit. The horse should receive one cycle of treatment: 5 days of naphthalene, stop for 5 days, and 5 days of naphthalene treatment. Inorganic arsenic at 5 ppm in drinking water or salt with 35 to 40 ppm arsenic may protect the sulfur-containing structures of the body.[103]

11.13.1.2

Arsenic Poisoning

Arsenic commonly is found in some parasiticidal dips, weed and orchard sprays, insect baits, and arsenic-containing medications. Arsenic is a general tissue poison, and 1 to 5 mg/kg may be toxic to horses.[104] Signs of arsenic toxicosis include gastrointestinal disturbances, weight loss, and a dry, dull, easily epilated hair coat. Some horse may develop a long shaggy coat with severe seborrhea.

Diagnosis is based on history of ingestion of arsenic or an arsenic-containing compound and clinical signs. Definitive diagnosis may be difficult because the test of choice is the measurement of arsenic levels in kidney or liver (greater than 10 ppm).[60,104]

Treatment of arsenic toxicity is complicated by the peracute nature of the disease. One should wash off topically absorbable arsenic and should empty the digestive tract of the horse with the aid of laxatives. Orally administered sodium thiosulfate at 50 to 75 g every 6 to 8 hours binds unabsorbed arsenic. Intraveously administered sodium thiosulfate at 25 to 30 g of a 20% solution in distilled water may counterabsorb arsenic. Dimercaprol (BAL) is the classic antidote for arsenic toxicity and is effective if administered within hours of ingestion. Initial treatment is 5 mg/kg intramuscularly and then 3 mg/kg every 6 hours for the first day, followed by a dosage of 1 mg/kg intramuscularly every 6 hours for the next 48 hours. Intramuscular injections are painful.[105] One must identify the source of arsenic and eliminate it.

11.13.1.3

Mercury Poisoning

Mercury poisoning occurs when the horse ingests feed contaminated with fungicide or absorbs or ingests mercury from counterirritants.[60] Affected horses may have gastrointestinal disorders, depression, anorexia, weight loss, and emaciation. Generalized alopecia with subsequent loss of mane and tail hairs is common. Diagnosis is complicated because the sample of choice is kidney tissue, where mercury is concentrated. Orally administered potassium iodide at 4 g per day for 14 days may be beneficial in treating affected horses.[92]

11.13.1.4

Leucenosis Poisoning

Leucenosis is a toxicosis resulting from the ingestion of plants of the genus *Leucaena*.[60,105] In the United States, these plants are found in Hawaii. This plant contains a toxic amino acid (mimosine) that is a potent depilatory agent.

Horses with this toxicosis show a gradual loss of the mane, tail, and fetlock hairs. Severely intoxicated animals may undergo complete hair loss 7 to 14 days after exposure. Laminitis and hoof dystrophies have been reported.[60,105]

Diagnosis is based on history and clinical signs. One treats affected horses symptomatically after preventing further exposure to the plants. Ferrous sulfate 1% added to the feed may benefit affected horses and limit further hoof damage.[94]

11.13.2 HAIR FOLLICLE ABNORMALITIES

11.13.2.1 Mane and Tail Dystrophy

Mane and tail dystrophy may be congenital or acquired. Whether the condition is hereditary is unknown. Affected horses (juvenile or adult) have short, brittle, dull hairs on the mane and tail. No treatment is known, but the condition does not affect the health or function of the horse.

11.13.2.2 Black and White Follicle Dystrophy

Affected horses (juvenile and adult) have abnormal hairs growing in patches of white- or black-haired areas. These hairs are short, brittle, and dull. Affected areas may be hypotrichotic. No treatment is available. 705

706

11.13.2.3 Curly Coat

Curly coat is a hereditary condition of Percherons, Missouri Fox Trotters, and Bashkin Horse breeds that is inherited as an autosomal recessive trait. Clinically affected horses have unusually curly coats.

11.13.3 ENDOCRINE CAUSES OF HAIR ABNORMALITIES

11.13.3.1 Hyperadrenocorticism

Equine hyperadrenocorticism most commonly results from an adenoma or dysfunction of the pars intermedia of the hypophysis.[89,106] The abnormal pars intermedia secretes adrenocorticotropic hormone, α- and β-melanocyte–stimulating hormone, corticotropin-like intermediate lobe peptides, and β-endorphins.

Hyperadrenocorticism is most common in older horses (12 to 15 years old or older)[106–108] but is reported occasionally in horses 7 to 10 years of age. The first clinical sign noted by an owner is often a rapid regrowth of long hair after the shedding season or failure to shed the coat (Figure 11-33). The coat becomes shaggy, and body hairs can reach lengths of 10 to 12 cm. Interestingly, mane, tail, and fetlock hairs are unaffected. Secondary seborrhea may develop. Affected horses may be predisposed to dermatophytosis, dermatophilosis, or secondary bacterial pyoderma. Nondermatologic signs include polydipsia, polyuria, muscle wasting, lethargy, weight loss, pendulous abdomen, laminitis, and flaccid muscles. Neurologic disorders and blindness may develop.

Diagnosis is based on clinical signs and laboratory test results.[108–110] Complete blood counts often reveal neutrophilia, lymphopenia, and eosinopenia. Urinalysis may reveal a low specific gravity and occasionally glucosuria. A serum chemistry panel may reveal any combination of the following: hyperglycemia, hypercholesterolemia, and lipemia.[108] Definitive diagnosis of hyperadrenocorticism in horses caused by pituitary pars intermedia dysfunction is discussed elsewhere in this text.

Figure 11-33 Horse with pituitary-dependent hyperadrenocorticism. The long hair coat did not shed in the spring.

Treatment options for horses with hyperadrenocorticism include bromocriptine mesylate, cyproheptadine hydrochloride, and pergolide.[111] Unlike small animals, horses are not responsive to mitotane treatment. These treatment options are discussed elsewhere in this text.

11.13.3.2 Hypothyroidism

Hypothyroidism in the horse is rare, and much of the information on this endocrinopathy is anecdotal.[112–114] Horses with naturally occurring hypothyroidism reportedly have a wide range of clinical signs including loss of mane and tail hairs, muscle weakness, hyperpigmentaion, seborrhea, lethargy, poor performance, infertility, agalactia, myxedema, and dry, dull, brittle hair. Diagnosis and treatment of equine hypothyroidism is discussed elsewhere in this text.

11.13.4 MISCELLANEOUS DISORDERS AFFECTING THE HAIR COAT

11.13.4.1 Anagen Defluxion and Telogen Defluxion

Anagen defluxion refers to a condition in which a disease or drug interferes with anagen hair growth, resulting in abnormal hairs or hair shaft abnormalities or both. Hair loss occurs within days of the insult or drug. The condition occurs most commonly in horses with high fevers, systemic illnesses, or malnutrition[115] (Figure 11-34). Typically, the mane and tail are not affected.

Telogen defluxion refers to a condition in which a stressful situation causes the sudden cessation of anagen hair growth and the sudden synchrony of many hair follicles in telogen hair cycle stage.[115] Two to 3 months later a sudden shedding and a wave of new hair growth occur.

These conditions cannot be distinguished clinically. Diagnosis is based on examining the hair shaft of easily epilated hairs. Anagen defluxion is characterized by dysplastic hairs, the hair shaft may be weak or narrow, and the root end contains a root sheath. Telogen defluxion is characterized by uniform hairs with no shaft abnormalities and a nonpigmented root end lacking a root sheath. Both conditions resolve spontaneously when the animal recovers from the predisposing condition.

11.13.4.2 Trichorrhexis Nodosa

Trichorrhexis nodosa is an acquired hair shaft disorder of horses caused by physical or chemical trauma.[97] Overzealous grooming, shampoos, pesticides, alcohol, or solvents are the most common causes. The lesions are visible without magnification and appear as small white to gray nodules on the hair shaft. The hair shaft fractures and breaks easily at these sites. Microscopically, affected hairs have the appearance of two brooms shoved together. Therapy consists of identifying and eliminating the trauma. 706

707

Figure 11-34 Foal with telogen effluvium after illness.

11.13.4.3 Piedra

Piedra is a rare superficial fungal disease of horses that causes nodules on the hair shaft. Black or white filamentous nodules consisting of tightly packed hyphae most commonly are visible on the mane and tail. Affected hairs break at the site of infection. Definitive diagnosis is by fungal culture and microscopic identification of the agent, *Piedraia* sp. or *Trichosporon beigelii*. Treatment of affected horses includes clipping the hair and applying topical fungicides.

11.13.4.4 Abnormal Shedding

Photoperiod and temperature control shedding. Most horses have a spring and fall shed. Abnormal shedding in horses may result in large areas of alopecia.[97] Large areas of hair loss may develop on the face, shoulders, or even over the entire body. The pathogenesis is unknown. Skin biopsy is recommended to eliminate infectious or parasitic causes of hair loss. Skin biopsy is normal and shows normal hair follicles in various stages of development. Horses spontaneously recover in up to 3 months.[98]

11.13.4.5 Alopecia Areata

Alopecia areata is a rare idiopathic skin disease of horses characterized by focal areas of alopecia.[96] Lesions may be single or multiple, and the underlying skin is otherwise normal. If and when hair regrows, it may be a different color. Diagnosis is by biopsy. Classically, in early lesions, skin biopsy shows an accumulation of lymphoid cells around the proximal end of the anagen hair follicles.[97] This change is diagnostic but may require numerous biopsies before being observed. Prognosis is uncertain. In human beings, alopecia areata may resolve spontaneously in 3 to 5 years. Whether spontaneous resolution occurs in horses is unknown.

11.14 Mucocutaneous Vesicular Diseases

A vesicle is an elevated, fluctuant, fluid-filled lesion of less than 1 cm in size. A vesicular eruption suggests a viral, autoimmune, or irritant cause. In horses, vesicles are transient because the epidermis is thin and these lesions rupture easily. Erosions or ulcerations are often the first clue that a vesicle-producing disease is present. Additionally, vesicular diseases may masquerade as pustular eruptions. Vesicles in horses rapidly fill with inflammatory cells, making them indistinguishable from frank pustules. In rare instances, horses may develop bullae (>1 cm in diameter) or large vesicles. Occasionally, bullae fill with blood and are red-purple.

11.14.1 VIRAL CAUSES OF VESICULAR ERUPTIONS

11.14.1.1 Equine Herpes Coital Exanthema

Coital exanthema is a rare contagious venereal disease of horses cause by equine herpesvirus type 3, which occurs worldwide. The disease is transmitted via coitus, insects, fomites, and inhalation. Early lesions begin as papules that rapidly progress to vesicles or bullae or pustules on the vulva or perineum of mares and the penis and prepuce of stallions.[116] Vesicles and bullae also may be present in the mouth or nostril or on the lips. Affected areas commonly become eroded and ulcerative. Lesions are more often pruritic rather than painful.

Depigmentation often occurs in areas where lesions have developed and healed. Stress may precipitate recurrences.

Diagnosis is based on the appearance of lesions on the vulva, perineum, penis, or prepuce; skin biopsy; and virus isolation. Histologic findings include hyperplastic superficial and deep perivascular dermatitis with ballooning degeneration and eosinophilic intranuclear inclusion bodies.

Treatment is symptomatic, but corticosteroids are contraindicated. Owners should isolate affected horses and remove broodmares and stallions from the breeding program for a minimum of 4 weeks. The disease has no known effect on fertility.

11.14.1.2 Vesicular Stomatitis (Sore Nose and Sore Mouth)

Vesicular stomatitis is caused by a rhabdovirus with two major serotypes: New Jersey and Indiana.[117] The 707
disease affects horses, cattle, and swine and is enzootic in North, Central, and South America. In North 708
America, the disease is reportable.

The disease has a seasonal occurrence in summer and fall and is believed to be transmitted to horses by insect bites. Within a group of horses, however, the disease may be transmitted via direct contact. The incubation period is short (24 to 72 hours), and lesions may last for only 3 to 4 days. Infected horses rapidly develop vesicles up to 2 cm in diameter in the mouth and on the lips. These lesions rupture, leaving large painful erosions and ulcers. Affected animals salivate profusely, and fever and anorexia are common. Rarely, lesions develop on the hooves, prepuce, and teats.

Diagnosis confirmation is by serologic examination. Histologic findings are nonspecific and include a hyperplastic epidermis, inter- and intracellular edema of the epidermis, reticular degeneration, spongiotic microvesicles, and focal necrosis. Superficial and deep perivascular dermatitis is present.

Owners should feed affected horses a soft gruel until oral lesions heal, usually within a few days. Permanent depigmentation may occur in areas of former ulceration. Infection results in immunity for up to 6 months.

11.14.1.3 Horsepox

Horsepox is uncommon and has been reported only in Europe. Horsepox is a benign disease, caused by an unclassified poxvirus.

The virus gains access to the body by the respiratory tract or the skin.[118] Systemic spread occurs by the lymphatics. Poxvirus inoculated into the skin may multiply locally, directly enter the blood, and create a primary viremia. The virus causes degenerative changes in the epithelium as a result of virus replication and results in development of vesicular lesions. Poxviruses also cause epithelial hyperplasia by stimulating host-cell DNA synthesis before the onset of cytoplasmic virus-related DNA replication. Ischemia and necrosis occur in the dermis and subcutaneous areas as a result of vascular damage.

Clinical lesions of equine poxvirus infections develop as follows. An erythematous maculopapular eruption develops, followed by the development of vesicles. This stage is transient and may not be observed. Vesicles develop into umbilicated pustules with a depressed center and a raised erythematous border. When the pustule ruptures, a crust develops and the lesion heals, often with scarring.

Horsepox may affect horses of any age. The disease is transmitted by direct contact with an infected host or with contaminated grooming tools or tack. Lesions of horsepox are typically vesicles and umbilicated pustules with crusts. Three clinical presentations (oral, leg, and vulvar) have been described.[64] Oral horsepox (buccal horse pox, contagious pustular stomatitis) is characterized by the development of lesions on the inner lips and buccal mucosa. In severe forms, pox lesions may develop in the pharynx, larynx, nostrils, or all of these sites. Leg pox usually develops on the pasterns and fetlocks and often is confused with “scratches” or “greasy heel.” Pain and lameness are common. Vulvar pox (genital horsepox) is uncommon, occurring predominantly in severely affected animals. One may observe pyrexia and anorexia early in the course of the three forms of horsepox.

Diagnosis is based on history and clinical signs, and confirmation is by histologic examination. Intracytoplasmic inclusion bodies demonstrated by routine histopathologic examination of tissue or electron microscopy are diagnostic. Other findings include ballooning degeneration of the epidermis (stratum spinosum), reticular degeneration, acantholysis (loss of cohesion of cell in the granular area), intraepidermal microvesicles, a superficial and deep perivascular dermatitis, and intraepidermal microabscesses and pustules.

Treatment is symptomatic. Most horses recover in 2 to 4 weeks. Occasionally, the disease is fatal in severely affected young horses. Recovery produces lifelong immunity. This disease affects human beings and cattle.

11.14.2 AUTOIMMUNE DISEASES CAUSING VESICULAR LESIONS

Bullous pemphigoid is a rare autoimmune skin disease of horses characterized by the development of vesicles and ulceration of the oral mucosa and occasionally the skin. Bullous pemphigoid is caused by production of an autoantibody (pemphigoid antibody) against a component in the basement membrane of the skin and mucous membranes.[56] The pemphigoid antibody binds to the basement membrane zone and complement fixation occurs, resulting in production of inflammatory mediators chemotactic for neutrophils and eosinophils. These cells release proteolytic enzymes that disrupt the dermal-epidermal cohesion, separation occurs, and a vesicle forms.

In horses, vesicles and bullae develop at the mucocutaneous junction in the axillary or inguinal regions or in the oral cavity.[96] Skin lesions occur in the axilla and groin. Vesicles and bullae rupture easily and often are crusted and secondarily infected with bacteria. Pain, pruritus, anorexia, fever, and salivation are common.

Definitive diagnosis is by eliminating other causes of vesicular lesions from the differential list and by skin biopsy. Biopsy of a vesicle or intact bullae is essential; biopsy of crusted or ulcerative lesions will be nondiagnostic. Bullous pemphigoid is characterized by subepidermal vacuolar alterations and subepidermal clefts and vesicles.[36] Neutrophilic and eosinophilic infiltration of the superficial epidermis is common. If one 708
performs direct immunofluorescence testing and the results are positive, one observes a linear deposition of 709
immunoglobulin at the basement membrane zone. Direct immunofluorescence testing is not recommended.

Few reports exists of treatment of bullous pemphigoid in horses.[36,57,96] Treatments have included an initial large dose of prednisolone (1 mg/kg orally every 12 hours) or dexamethasone (0.2 mg/kg orally every 24 hours) to induce remission. After the arrest of new lesion development and healing, one institutes maintenance therapy with alternate-day administration of glucocorticoids at the smallest effective dose. Therapy must be individualized and most likely will be lifelong. The use of adjuvant therapy (e.g., gold salts or azathioprine) has not been reported in horses with bullous pemphigoid but may be useful.

11.14.3 IRRITANT AND TOXIC CAUSES OF MUCOCUTANEOUS VESICLES

Irritant reactions, toxic chemicals, or allergic reaction to drugs may result in oral mucocutaneous vesicles. One should suspect these causes when lesions develop acutely in the absence of signs of systemic illness, in single animals within a herd, or in horses receiving medications or counterirritants. Mercurial compounds (commonly used in counterirritants) also can cause generalized hair loss, lameness, and emaciation in chronically intoxicated animals. Creosol and cantharidin beetles are common causes of oral ulcers. Foreign bodies such as grass awns may cause mucocutaneous ulceration and vesicles.

11.14.4 VASCULITIS

Oral ulcers may develop in horses with vasculitis (see the section Vasculitis and Purpura Hemorrhagica).

11.15 Necrotizing Skin Disorders

Necrotizing skin diseases develop from a wide range of causes. The unifying characteristic is that each of these diseases may cause local or widespread full-thickness death of the skin, sloughing of tissue, ulceration, and exudation. Definitive diagnosis of the underlying cause may be difficult in some cases.

11.15.1 DECUBITAL ULCERS (PRESSURE SORES, SETFASTS, SADDLE GALLS, AND SADDLE SORES)

Decubital ulcers or sores are caused by prolonged application of pressure to an area. Thin and emaciated animals are at greatest risk for development of decubital ulcers.

Pressure sores may develop from poorly fitting tack on the back, neck, or girth of the horse; from recumbency during surgery, even while on suitable bedding; and from casts, leg wraps, or elastic bandages that have become wet or are unevenly wrapped, too tight, or ill-fitting. The amount of pressure required to create a decubital ulcer is not great. Tack and saddles may cause lesions over bony prominences or other areas subjected to extended pressure. Capillary circulation is stopped or severely limited, resulting in tissue anoxia and retention of metabolic wastes with tissue damage and death. Most lesions begin as small areas of tissue necrosis and progress to areas of ulceration. Secondary infections are common.[60]

Clinically, early lesions begin with hair loss, swelling, and erythema. A red-purple area of tissue discoloration may be visible. Within a few days, oozing, necrosis, and ulceration become visible. In severe cases, the skin loses its elasticity, subcutaneous tissues slough, and the skin may harden. Strands of living tissue may be attached to necrotic tissue. Lesions are often malodorous. Healed lesions tend to scar, and leukotrichia or leukoderma are common sequela.[92]

Diagnosis is based on history and clinical examination. Areas of skin that have lost sensation or have a parchmentlike feel should be suspect.

Treatment of these lesions is difficult. Because of significant capillary and venous congestion, systemic antibiotics are often not effective.[60,92] Wounds are managed best topically. One should clean the wounds daily with copious amounts of water to remove tissue debris and stimulate circulation and should use topical antibiotic

creams or ointments (i.e., iodine and chlorhexidine) to prevent secondary infection and to prevent the wound from becoming desiccated. Reepithelialization and wound healing greatly improve with the use of surgical dressings, but bandaging some lesions may be difficult. Surgical debridement and skin grafting may be indicated in some cases.

11.15.2 GANGRENE

Gangrene is a clinical term used to describe wet or dry tissue necrosis. Gangrene may result from external pressure, severe edema, burns, frostbite, snake bites, vasculitis, ergotism, fescue toxicosis, or bacterial or viral infections.[60] The characteristic lesion results from occlusion of the venous or arterial blood supply.

Dry gangrene occurs when the arterial blood supply to an area is occluded but the venous or lymphatic drainage is intact. Wet or moist gangrene is caused by occlusion or impairment of lymphatic and venous drainage plus putrefaction caused by a bacterial infection. Lesions of dry gangrene are dry, leathery, discolored, sunken, and cold to the touch. The skin may take a long time to slough. Lesions of wet gangrene are swollen, discolored, and malodorous.

Diagnosis is most often made by clinical examination, and confirmation is by biopsy. One must identify and treat the primary cause of gangrene. 709

710

11.15.3 THERMAL INJURIES

11.15.3.1 Burns

Excessive heat (burns) can occur from barn fires, brush fires, accidental spillage of hot solutions, lightning, electrocution, rope burns, counterirritants, or radiation. Barn fires cause most burns in horses.

Large thermal injuries in horses are difficult to manage.[119–122] The large surface area of the burn dramatically increases the potential for the loss of fluids, electrolytes, and caloric losses. Burns on 50% or more of the body are usually fatal, but this depends on the depth of the burn.[119,122] Massive wound contamination is almost impossible to prevent because of the impossibility of maintaining a sterile environment.[118,121] Horses require long-term restraint to prevent continued trauma; wounds are often pruritic and self-mutilation is common.[120] Burned horses frequently are disfigured, preventing them from returning to full function.

Burns are classified by the depth of the injury.[119–122] First-degree burns involve only the most superficial layers of the epidermis. These burns are characterized by erythema, edema, desquamation of superficial layers of the skin, and pain. The germinal layer of the epidermis is spared, and these burns heal without complication.[121] Second-degree burns involve the entire epidermis and may be superficial or deep. Superficial second-degree burns involve the stratum corneum, stratum granulosum, and a few cells of the basal layer. Deep second-degree burns involve all layers of the epidermis. Clinically, these burns are characterized by erythema, edema at the epidermal-dermal junction, necrosis of the epidermis, accumulation of white blood cells at the basal layer of the burn, eschar (slough produced by a thermal burn) formation, and minimal pain. The only germinal cells spared are those within the ducts of sweat glands and hair follicles. Second-degree burns heal well with good wound care.[121] Third-degree burns are characterized by loss of epidermal and dermal components. Fluid loss occurs, along with significant cellular response at the margins and deeper tissue, eschar formation, lack of pain, shock, wound infection, and possible bacteremia and septicemia.

Healing is by contraction and epithelization and occurs only from the wound margins. Infection and problems with wound healing frequently complicate these burns.[121] Fourth-degree burns involve all the skin and underlying muscle, bone, and ligaments.

Burns cause local and systemic effects.[120–123] Local tissue damage results from massive protein coagulation and cellular death. In the immediate area of the burn, arteries and venules constrict and capillary beds dilate. Capillary wall permeability increases in response to vasoactive amines released as a result of tissue damage and inflammation.[122] These vascular responses result in fluid, protein, and inflammatory cells accumulating in the wound. Vascular sludging, thrombosis, and dermal ischemia occur, resulting in further tissue damage. The tissue ischemia continues for 24 to 48 hours after the injury and is believed to be caused by the local release of thromboxane A_2.[121,122] Lipid layers in the skin are destroyed, and a fourfold increase in the loss of fluid occurs. Fluid losses result in increased heat loss from evaporation and an increased metabolic rate. The full extent and depth of the burn may not be evident for several days. Neutrophil function and chemotaxis greatly decrease, predisposing the wound to local infection, bacteremia, and septicemia. The following microorganisms frequently colonize burns: *Pseudomonas aeruginosa, Staphylococcus, Escherichia coli, Klebsiella* spp., nonhemolytic *Streptococcus* spp., *Proteus* spp., *Clostridium* spp., and *Candida* spp.[118–121] Systemic effects are life-threatening and include hypovolemia, fluid and electrolyte losses, protein loss, pulmonary edema, anemia, increased basal metabolic rate, increased caloric needs, and depressed cell-mediated and humoral immune responses. Hypovolemia exacerbates a decrease in cardiac output following a circulating myocardial depressant factor.[123]

One should treat first-degree burns and superficial second-degree burns immediately with ice or cold water to prevent further tissue necrosis.[118,121] One should apply aloe vera cream or a water-soluble antibacterial cream to the wound to prevent infection. In addition, one should administer nonsteroidal analgesics to alleviate pain and to help reduce dermal ischemia. Aspirin at 10 to 20 mg/kg orally once or twice daily decreases thromboxane production, may halt further dermal ischemia, and may be the initial drug of choice.[121]

One manages deep second-degree burns initially as described previously; however, these burns tend to form blisters that should be left intact as long as possible because the vesicular fluid is a good medium for reepithelialization.[119–121] One should trim ruptured blisters, clean the area with copious amounts of water, and cover the wound with an antibacterial dressing or xenograft or allow an eschar to form.[119–122] The bandage should allow drainage and should be changed at least daily.

One may manage full-thickness burns (third and fourth degree) by occlusive dressing (closed technique), eschar production (exposure technique), continuous wet dressings (semiopen technique), or excision and grafting techniques.[122] The most practical therapy for large burns in horses is the semiopen method, leaving the eschar intact with continuous application of moist bandages and antibacterial agents. The moist dressings help prevent heat and moisture loss from the eschar, provide protection of the eschar, and help prevent bacterial invasion in the wound.

Routine use of systemic antibiotics is not recommended in burn patients. Short-term systemic antibiotics may 710
be useful in the initial 3 to 5 days after the burn to minimize bacterial colonization of burns and systemic 711
sepsis.[122] In the absence of sepsis, systemic antibiotics are contraindicated. Extensive use of antibiotics may cause altered microbial flora in the gut and in mucous membranes, which may predispose the patient to infections from antibiotic-resistant gram-negative bacteria or from fungi.[124] Topical medications should be water-based, should be applied and removed easily, should not interfere with wound healing, and should be

excreted or metabolized readily. Silver sulfadiazine and aloe vera are effective. Silver sulfadiazine is effective against gram-negative bacteria, causes no discomfort to the horse, penetrates eschar, and has a 24-hour duration of action Aloe vera is reported to relieve pain, decrease inflammation, stimulate cell growth, and kill bacteria and fungi. Aloe vera is most useful in the early treatment of wounds. Several excellent references for further information on long-term medical and surgical management of horses with large thermal burns are available.[119,121,122]

11.15.3.2 Frostbite

Frostbite occurs when tissue is exposed to extreme cold. Sick, debilitated, and neonatal animals are at increased risk. Cold temperatures inhibit cell metabolism and cause tissue dehydration, cell disruption by ice crystals, ischemia, and vascular damage. The most commonly affected areas are the glans penis, ear tips, coronary bands, and heels.[60] The initial lesion of frostbite is paleness of the skin. Erythema, scaling, and hair loss follow. Pigment loss may occur. In severe cases, necrosis and dry gangrene occur.

Mild cases of frostbite do not require treatment. More severe cases require rapid thawing in warm water (41° to 44° C).[60] After rewarming, one should apply nonsteroidal antibiotic ointments to the area. In severe cases with necrosis and sloughing, topical wet soaks and symptomatic therapy with antibiotics may be needed to prevent sepsis. One should not attempt surgical debridement until an obvious demarcation is present between viable and nonviable tissue. Previously frostbitten areas may be more susceptible to cold injury.

11.15.4 CHEMICAL TOXICOSIS

In addition to causing disorders of the hair coat, selenosis may result in necrosis and sloughing of the hoof (see the section Chemical and Plant Causes of Coat Abnormalities).

11.15.5 STACHYBOTRYOTOXICOSIS

Stachybotryotoxicosis is a mycotoxicosis caused by the toxins of the fungus *Stachybotrys atra*.[60] This fungus grows on hay and straw and produces toxins referred to as macrocytic trichothecenes. These toxins cause bone marrow suppression, profound neutropenia, thrombocytopenia, and necrotic-ulcerative lesions of the skin and mucous membranes.

Commonly, lesions begin at the mucocutaneous junction as focal areas of necrosis and ulceration. Petechiae, ulcers, large areas of necrosis, catarrhal rhinitis, suppurative rhinopharyngitis, and laryngitis follow. Skin lesions occur as early as 24 hours after ingestion of the toxin. Systemic signs include lethargy, anorexia, weight loss, hyperactivity, proprioceptive deficits, colic, muscular stiffness, and second-degree atrioventricular block. Affected animal develops hemorrhagic diathesis, hemorrhagic enteritis, and septicemia and die.

Diagnosis is based on history, clinical signs, and finding the toxin in the feed. If one recognizes toxicosis early in the course of the disease, withdrawal of affected feed has resulted in resolution of signs. Animals with extensive lesions and chronic exposure have a poor prognosis.

11.15.6 BITES AND STINGS OF VENOMOUS INSECTS, SPIDERS, AND REPTILES

Many species of snakes, spiders, and insects have venomous bites and stings. Except for snake bites, these animals lack sufficient quantity of venom to cause more than transient pain or local inflammation. Venoms contain a variety of substances, including enzymes, peptides, polypeptides, amines, and glycosides, that act locally by causing tissue necrosis and vascular thrombosis and hemorrhage or systemically by causing widespread hemolysis and neurotoxicity.

11.15.6.1 Snake Bite

Of the poisonous snakes in the United States, bites from rattlesnakes, water moccasins, and copperheads occur most commonly in horses.[125] The venom from snakes is hemotoxic and proteolytic and produces extreme local swelling with significant tissue and red blood cell destruction.

Most bites occur in the spring and summer. Horses most commonly are bitten on the nose, head, neck, and legs. Snake bites may or may not involve envenomation and may be dry or wet. Bites in which no venom is injected swell minimally and are only slightly painful (dry bite). When envenomation occurs (wet bite), rapid swelling, pain, and local hemorrhage develop, usually within 60 minutes of the bite. Fang marks are often difficult to find because of tissue swelling. Edema, erythema, and tissue necrosis develop over days, and the skin may slough (Figure 11-35). Bites occurring on the face or head are serious because of the risk of respiratory and nasal edema. If respiratory distress is severe, the horse may need a tracheotomy.

One treats snake bites symptomatically. One should clean the wound and provide hydrotherapy with cold water to minimize swelling. If swelling is already present, warm hydrotherapy may stimulate circulation and 711
removal of tissue edema. Whether this increases the absorption of venom in the early stages of the bite is 712
unknown, however. Broad-spectrum antibiotics are indicated to prevent secondary infection. The use of glucocorticoids is controversial but may be beneficial in decreasing inflammation and pain. Nonsteroidal antiinflammatory agents also may be beneficial. Surgical debridement and wound closure may be necessary if severe necrosis and sloughing occur. Although specific antivenoms are available, they are of limited use. Maximum benefit is attained only when they are administered within hours of the bite. Additionally, the volume of antivenom necessary to treat snake bites in horses may be cost-prohibitive.

Figure 11-35 Face of a horse after being bitten by an Eastern diamondback rattlesnake.

11.15.6.2 Fire Ant Bites

Fire ants, *Solenopsis* spp., are common in the southern United States. Single or small numbers of stings are acutely painful and rapidly develop into a pustule or crust. Horses are bitten most commonly on the legs, nose, and ventrum, but massive exposure can occur if the horse rolls on an anthill and is bitten by hundreds or thousands of ants. Complications of massive exposure include infection, anaphylactic shock, bronchospasms, and sloughing of the epidermis. Single or multiple small numbers of solitary stings usually require little or no treatment. Applying an antibiotic ointment to minimize the chance of myiasis is prudent, but otherwise wounds heal without complication. If massive exposure has occurred, one may need to use systemic antibiotics and nonsteroidal antiinflammatory drugs to decrease pain and swelling.

11.15.6.3 Spider Bites

Black, brown, and red widow spiders *(Latrodectus* species) and the brown recluse *(Loxosceles reclusa)* spider are common in America. In Australia, the black house spider *(Ixeuticus)* causes painful bites.[125] Spider bites are characterized by hot, edematous, painful swellings in the area of the bite. The brown recluse spider has a dermal necrotoxin that may cause severe dermal necrosis, but this has not been reported in horses.

Treatment is symptomatic. Cold ice packs applied to the area and systemic glucocorticoids or antihistamines, or both, may be helpful. Spraying the environment of the horse with a parasiticide is important. One should remove discarded furniture, newspapers, old cloths, and trash from the premises because these are favorite living areas for venomous spiders.

11.15.7 VASCULITIS AND PURPURA HEMORRHAGICA

Vasculitis is an inflammatory reaction occurring in the wall of the blood vessel (Figure 11-36). Vasculitides are classified by inflammatory cell type. Neutrophilic vasculitides are subdivided further into leukocytoclastic (neutrophil nuclei undergo karyorrhexis) or nonleukocytoclastic.

The immunologic mechanisms involved are typically type I and type II hypersensitivity reactions.[59] Equine viral arteritis, equine influenza, *Corynebacterium pseudotuberculosis,* and *Streptococcus* spp. (especially *S. zooepidemicus* subsp. *equi*) infections may result in vasculitis.[34] Vasculitis also may occur following 712
Rhodococcus equi pneumonia, bronchopneumonia, cholangiohepatitis, and some antibiotic treatments. Often the 713
underlying cause is not identified.

Figure 11-36 Horse with vasculitis resulting from strangles.

Idiopathic vasculitis has no known breed, sex, or age predilection. The most common locations for lesions are the distal limbs, ears, lips, and periocular areas.[36] Oral ulcers and bullae may be present. Skin lesions consist of purpura, edema, and erythema. Systemic signs may include pyrexia, depression, anorexia, weight loss, and lameness.

Purpura hemorrhagica is an acute noncontagious disease of horses characterized by extensive edema and hemorrhage of the subcutaneous tissue. Hemorrhage in the mucosae and viscera are common. Most cases occur following strangles or equine influenza.[36] Clinical signs usually develop within 2 to 4 weeks of the respiratory infection. Urticaria followed by pitting edema of the distal limbs, head, and ventral abdomen is common. Severe edema of the head may compromise breathing.[16] Tissue exudation and sloughing may occur. Pain and pruritus are rare. Affected horses usually are depressed, reluctant to move, and often anorectic.

Diagnosis of vasculitis is by skin biopsy. Obtaining skin biopsy specimens from lesions 8 to 24 hours of age is important because these lesions tend to have the most diagnostic changes. Lesions more than 24 hours old may be nondiagnostic because of intense secondary cellular infiltrates or necrosis. Skin biospy reveals neutrophilic, eosinophilic, lymphocytic, or mixed cellular infiltrates in the vessel wall. Fibrinoid degeneration and hemorrhage are common.[64] Direct immunofluorescence testing is occasionally useful as an adjunct diagnostic aid.

Prognosis for horses with vasculitis is unpredictable.[126] Therapy of vasculitis is discussed elsewhere in this text.

11.15.8 PANNICULITIS AND FAT NECROSIS

Panniculitis refers to inflammation of the subcutaneous fat. This condition is rare in horses and results from widespread death of lipocytes. Fat cells are vulnerable to trauma, ischemia, and neighboring inflammation. When lipocytes are damaged, lipid is released and undergoes hydrolysis into glycerol and fatty acids. Fatty acids are potent inflammatory agents that elicit further inflammatory reactions.[127]

Panniculitis may be precipitated by a wide range of causes including trauma, infections, autoimmune disease, pancreatic disease, glucocorticoid therapy, vasculitis, vitamin E deficiency, and idiopathic causes. In the horse, few cases have been reported, and the causes of those were obscure. Vitamin E deficiency was suspected in a few horses.[82]

Clinically, horses with panniculitis show deep-seated nodules and plaques.[127] Lesions may be single or multiple and vary in size. Nodules may be hard and well-defined or soft and ill-defined. Initially, lesions are not fixed to the overlying skin, but as the disease progresses, nodules become cystic and rupture onto the skin surface. The ulcerating nodules drain a yellow to brown to bloody oily material. Pain varies. Healed lesions may leave depressed scars. Affected animals may be febrile, depressed, lethargic, and anorectic.

Definitive diagnosis is by skin biopsy. One should obtain samples for histopathologic evaluation by deep excisional biopsy using a scalpel blade because skin biopsy punches do not obtain sufficiently deep samples to be diagnostic. One should request special stains (i.e., positive acid–Schiff, Gomori's methenamine silver, Brown and Brenn) for causative agent. Skin biopsy reveals lobular to diffuse pyogranulomatous inflammation in the panniculitis.

One should identify and treat underlying causes appropriately. Idiopathic panniculitis may respond well to prednisolone at 1 to 2 mg/kg orally once daily for 7 to 14 days or to a single treatment of dexamethasone at 20 to

30 mg intramuscularly.[82,127] Clinical improvement usually occurs within 7 to 14 days. Relapses occur, and the horse may require lifelong therapy.

11.16 Dermatosis Of The Lower Limb

Skin diseases of the lower limbs of horses are common dermatologic problems. These diseases may be extensions of generalized dermatoses or unique clinical syndromes.

11.16.1 INFECTIOUS DISEASES OF THE LOWER LIMB

11.16.1.1 Bacterial Pastern Folliculitis

Bacterial folliculitis of the pastern is caused by *Staphylococcus aureus, Staphylococcus hyicus,* or β-hemolytic streptococcus.[92,125] This disease is considered a primary pyoderma, but the mechanism by which organisms initiate disease is unknown.

Lesions are limited to the posterior aspect of the pastern and fetlock region and may affect single or multiple limbs. The initial lesion consists of papules and pustules that eventually coalesce and produce large areas of ulceration and suppuration. The disease is not associated with systemic signs.

Diagnosis is by clinical signs, skin scrapings, cytologic examination of the exudate, Gram stain, and bacterial culture and sensitivity. Cytologic examination of pustule contents usually reveals large numbers of neutrophils engulfing bacteria.

Sedation may be necessary for initial treatment because lesions are painful.[125] One should clip hair from affected areas and wash the area daily in an antimicrobial scrub or shampoo (e.g., chlorhexidine shampoo or 713
scrub) and should apply an appropriate antibiotic ointment without corticosteroids twice daily. Systemic 714
antibiotic therapy is not usually necessary.

11.16.1.2 Ulcerative Lymphangitis

Ulcerative lymphangitis is a bacterial infection of the cutaneous lymphatics of horses. Lesions are most common on the hindlegs, especially distal to the hock, and consist of hard to fluctuant nodules that abscess, ulcerate, and drain pus. Individual nodules may heal, but new lesions develop. Cording of the regional lymphatics, edema, and fibrosis are common. Regional lymph nodes usually are not involved.

Definitive diagnosis is by direct smear, Gram stain, and culture of a nodule. Skin biopsy reveals superficial and deep perivascular dermatitis that may be suppurative or pyogranulomatous. Special stains (Brown and Brenn, and Gram) may reveal the organism.

If one treats the disease early, therapy may be effective and may prevent permanent disfigurement and debilitation. The drug of choice pending culture and sensitivity is procaine penicillin 20,000 to 80,000 IU/kg intramuscularly every 12 hours for 30 days or longer. Adjunct hydrotherapy may be beneficial. After fibrosis develops, prognosis is poor.[125] One should clean the affected area daily with copious amounts of water and wash it with an antimicrobial scrub (e.g., chlorhexidine).

11.16.1.3 Viral Papillomatosis

Equine viral papillomatosis (warts) is caused by a DNA papovavirus.[118] Viral papillomatosis is common in horses and occurs most frequently in horses less than 3 years of age. No sex or breed predilection exists. Transmission appears to be by direct contact. Groups of young horses often are affected more frequently than horses of the same age housed individually. Lesions are most common on the muzzle, genitalia, and distal legs and are usually multiple and resemble papillomatosis of other species.

Definitive diagnosis is by skin biopsy. Epithelial proliferation without connective tissue proliferation is typical.

Benign neglect is the best treatment for these lesions; spontaneous remission almost always occurs. One should consider surgical removal only when the lesion interferes with function. Anecdotal reports that surgical removal or damage to part of the lesion induces remission of the lesion are unproven.[93] In fact, controlled studies suggest that such intervention might increase the duration of the lesions.[93,125] Efficacy of autogenous vaccines is unproven.

11.16.1.4 Sporotrichosis

The dimorphic fungus *Sporothrix schenckii* causes sporotrichosis, which was discussed in detail under Infectious Causes of Nodules.

A cutaneous lymphatic form of sporotrichosis may localize to the distal extremities of horses. The lymphatics become corded, and large nodules ulcerate and drain a thick brown-red discharge. Regional lymph nodes are not involved. Edema is rare. Diagnosis and treatment have been discussed previously.

11.16.2 PARASITIC DISEASES OF THE LOWER LIMB

The common parasitic diseases of horse have been discussed previously (see Parasitic Skin Diseases). Infestations of lice, *Chorioptes* spp., and chiggers are the most common parasitic dermatoses that cause lower limb pruritus.

11.16.3 NEOPLASTIC AND NONNEOPLASTIC PROLIFERATION DISEASES OF THE LOWER LIMBS

11.16.3.1 Keloids

A keloid is a nonneoplastic fibroblastic response that occurs on the pastern of horses. Clinically, the keloid resembles a cluster of grapes. Definitive diagnosis is by biopsy. These lesions do not respond to surgical excision, and in fact surgery may exacerbate them.[89,125] The best treatment for keloids is by intralesional injection of triamcinolone acetonide (not to exceed 20 mg per horse). Unfortunately, most lesions are so massive that response to therapy is poor.

11.16.3.2
Hemangiomata

Hemangiomata are benign tumors of the endothelial cells of blood vessels. Lesions occur most commonly in horses less than 1 year of age, and some horses are born with them.[93] Hemangiomata tend to be solitary tumors occurring on the distal limbs. The clinical appearance varies and may be circumscribed, nodular, firm to fluctuant, blue to black in color, dermal or subcutaneous, hyperkeratotic, or verrucous. Ulceration and bleeding are common.

Diagnosis confirmation is by skin biopsy, which reveals proliferation of blood-filled vascular spaces lined by single layers of well-differentiated endothelial cells.[37,93] Equine hemangiomata are characterized by a multinodular capillary hemangioma with hyperplasia and hyperkeratosis of the overlying epidermis.

Surgical excision is the treatment of choice. Equine verrucous hemangioma is difficult to excise, and cryosurgery may be beneficial. Recurrence is common.

11.16.4
AUTOIMMUNE DISEASES OF THE LOWER LIMBS

11.16.4.1
Pemphigus Foliaceus

Pemphigus foliaceus was discussed under Immunologic Causes of Exfoliation. In some horses the condition affects only the coronary band.[51] The coronary band of all four limbs is crumbly, degenerating, and exudative. Pain, lameness, and edema of the lower limb may occur. 714

715

11.16.4.2
Systemic Lupus Erythematosus

Systemic lupus erythematosus is a multisystemic autoimmune disease that is rare in horses. Profound lymphedema of the lower limbs may be the only clinical sign. One treats the disease with immunosuppressive doses of prednisone (2 mg/kg orally every 12 hours). The prognosis is grave.

11.16.4.3
Vasculitis

Vasculitis was discussed earlier under Vasculitis and Purpura Hemorrhagica. In some horses, cutaneous vasculitis is restricted to the white skin of the pasterns and face of horses in the summer.[51] Characteric lesions are erythema, swelling, pain, and exudation, and lesions may resemble photodermatitis, which suggests a photoinduced cause. Edema of the pastern and face is significant.

11.16.4.4
Pastern Dermatitis (Greasy Heel and Scratches)

Skin disease of the lower limbs is a common and frustrating problem in horses. *Pastern dermatitis, scratches, greasy heel,* and *mud fever* are colloquial terms for a moist exudative dermatitis of the caudal heel and pastern area. One must remember that these terms are nonspecific and describe a variety of inflammatory skin conditions of the lower limbs of horses.

The pathogenesis of this syndrome is not understood completely. The initial lesion may be a primary infection or may follow a predisposing factor such as pemphigus foliaceus or mites. Horses with long fetlock hair or

horses housed in muddy paddocks, unsanitary conditions, or rough stubbly pasture are at risk for pastern dermatitis. The problem is common in horses worked on tracks consisting of grit particles, which can cause microtrauma to the skin.

Clinical signs depend greatly on whether the condition is acute or chronic and whether the owner has treated the lesions. Many horse owners do not recognize the acute development of skin diseases, minimizing the opportunity to identify the underlying cause. To complicate matters further, many owners treat these lesions before seeking veterinary care. Many common over-the-counter medications can induce irritant or allergic reactions, making distinguishing between these reactions and the original skin disease almost impossible.

Regardless of the cause, clinical signs are similar (Figure 11-37).[125] Acute lesions usually begin at the heel. Pain, swelling, moist exudation, and hair loss are common. As the disease process continues, lesions spread proximally and anteriorly. Matting of the hair occurs, and the horse may be noticeably lame. Crusting is common. If the underlying disease process involves a vasculitis, ulceration may be present. If the disease is left untreated, a foul odor develops. Because of the constant flexion in the area, fissures often develop. In Draft Horses, vegetative granulomatous growths commonly result. Lesions may occur on one or multiple limbs or just on extremities with white markings.

Figure 11-37 Pastern dermatitis.

Definitive diagnosis requires a complete medical history. Liver function tests are essential in any horse in which the lesions are limited to the unpigmented areas of the skin. One should perform *Dermatophilus* preparations, fungal cultures, and skin scrapings in all cases. In horses with long hairs on the fetlocks, one should comb the hair thoroughly with a fine-toothed metal comb, which is often the only successful method for finding lice. In difficult cases, one should submit tissue samples for bacterial or fungal culture.

Correct therapy requires identifying the underlying cause. The reader can find specific therapy for most of the diseases elsewhere in this chapter or in the references. In all cases, one should clip the long hairs of the fetlock area and thoroughly wash the affected area with an antimicrobial scrub (e.g., 2% chlorhexidine). One should avoid iodine preparations because they can be irritating. One should remove all crusts and exudation, daily if necessary, and should avoid exposing the horse to moistures and irritants. Horses with idiopathic greasy heel often respond well to cleaning of the area, improved hygiene of the stall, and systemic corticosteroid therapy

(assuming bacteria are not the cause). Large doses of prednisolone (e.g., 1 mg/kg orally once daily) may be necessary to induce remission of clinical signs. One should not decrease the dose of glucocorticoids too rapidly or relapse may occur. If oral prednisolone does not induce remission, dexamethasone at 0.02 to 0.04 mg/kg orally once daily for 3 to 5 days may be effective.

11.17 Systemic Diseases With Cutaneous Manifestations

Reviewing all the skin diseases that may have systemic clinical signs is beyond the scope of this chapter. The 715
author has made an effort to include the most common systemic findings in this chapter. Table 11-3 provides a 718
brief summary.

TABLE 11-3 Skin Diseases With Systemic Manifestations

DISEASE	CUTANEOUS SIGNS	SYSTEMIC SIGNS
ENVIRONMENTAL		
Gangrene	Wet: moist swelling, discoloration, malodorous, tissue decomposition	Depends on underlying cause; fever
	Dry: dry, discolored, leathery skin	
Burns	Superficial: erythema, edema, pain, vesicles	Shock, respiratory compromise
	Deep: necrosis, ulceration, anesthesia, scarring	
Selenosis	Painful coronary band, sloughing and necrosis of hoof, rough hair coat, progressive loss of long hairs of mane and tail	Lameness, weight loss
Arsenic poisoning	Severe seborrhea, ulcer, nonhealing wounds, hypertrichosis	Gastroenteritis, emaciation, variable appetite
Mercury poisoning	Progressive alopecia	Gastroenteritis, lameness, emaciation
Iodism	Severe dry seborrhea with or without hair loss	Cough, variable appetite, joint pain, seromucoid nasal discharge, lacrimation
Hepatogenous photosensitization	Erythema, edema, pruritus, pain, in white or light-skinned area; vesicles and bullae may progress to oozing, necrosis, and sloughing	Acute: hepatic encephalopathy, icterus, depression, decreased appetite Chronic: weight loss, depression neurologic signs
Ergotism	Swelling of coronary band, necrosis of feet, sloughing of ears, tail, feet	Lameness of hindlegs, fever, weight loss, poor appetite
Leucenosis	Hoof dystrophies, shedding of hair	Laminitis, lameness
Hairy vetch toxicosis	Cutaneous plaques and papules that ooze yellow pus; pruritus; hair loss	Conjunctivitis, anorexia, pyrexia, weight loss
BACTERIAL DISEASES		

Strangles	Limb edema; edema of lips, eyelids; petechial hemorrhages of mucous membranes and sclera	History of acute contagious upper respiratory infection; pyrexia, mucopurulent nasal discharge; abscesses in the mandibular or retropharyngeal lymph nodes
Corynebacterium pseudotuberculosis abscesses	Single or multiple deep abscesses that develop slowly or rapidly; 50% occur in the pectoral or ventral abdominal area; ventral midline edema	Pitting edema, depression, fever, lameness, internal abscess, prolonged fever, abortion
Dermatophilosis	Exudative crusted lesions on dorsal trunk, face, pastern, or coronets	Depression, fever, lethargy, poor appetite, weight loss, lymphadenopathy; lesions on legs may cause edema, pain, and lameness.
Actinobacillosis	Thick-walled abscess of soft tissue	In newborn foals, disease is a highly fatal septicemic disease, and skin lesions are rare.
Clostridial infections	Malignant edema: swelling at site of infection, pitting edema, local erythema; skin may become hot to touch, painful, or slough; crepitus	High fever, anorexia, muscle tremors, acute death possible within 24–48 hours
	Blackleg: hot, painful, swelling that progresses to a cold painful swelling with edema and subcutaneous emphysema	
Glanders (farcy) *Pseudomonas mallei* (not in United States)	Subcutaneous nodules begin most commonly on medial aspect of hock; lesions rapidly ulcerate and drain a honey-colored material; lymphadenopathy and cording of lymphatics is common	Respiratory infection that rapidly leads to death
FUNGAL DISEASE		
Histoplasma farciminosa (epizootic lymphangitis)	Unilateral nodules on face, head, neck and occasionally trunk; nodules initially are firm but rupture and exude light-green, blood-tinged exudate; large ulcer may form and lesions may spread bilaterally	Lacrimation, conjunctivitis, and respiratory signs may occur
PARASITES		
Lice	Pruritus, scaling, alopecia	Anemia in severe infestations with sucking lice

Black flies	Painful papules, and wheals that may become vesicular, hemorrhagic, and necrotic; lesion may be localized to ears or intermandibular areas	Toxin in bite can cause increased capillary permeability; depression, weakness, staggers, tachypnea, tachycardia, weak pulse, shock, and possible death
IMMUNE-MEDIATED DISEASES		
Atopy	Chronic pruritic urticaria, excoriations, alopecia, lichenification	Respiratory difficulty, especially on expiration
Pemphigus foliaceus	Crusts, scales, oozing, annular eruption, matting of the coat; lesions may be limited to coronary band	Depression, weight loss, poor appetite, pyrexia
Bullous pemphigoid	Vesicles and bullae in mouth, groin, and axilla; crusts, ulcers, and epidermal crusts	Anorexia, depression, fever
Systemic lupus erythematosus	Lymphedema, panniculitis, alopecia, leukoderma; scaling of face, neck, and trunk	Polyarthritis, thrombocytopenia, proteinuria, fever, depression, weight loss
Transfusion reactions and graft-versus-host disease (may occur in horse after unmatched blood transfusion)	Exfoliative to ulcerative dermatitis, ulcerative stomatitis	Diarrhea, increased heart and respiratory rates, lacrimation, muscle fasciculation
Erythema multiforme	Symmetric maculopapular lesions, urticaria that results in annular arciform or polycyclic shapes; wheals that do not disappear	Occurs following pregnancy, drugs, neoplasia, connective tissue disease, and infections or may be idiopathic
Vasculitis	Purpura, edema, erythema, necrosis, crusts; purpura hemorrhagica causes edema and hemorrhagic swelling in tissue, mucosa, and viscera	May occur following strangles or influenza; depression, fever, reluctance to move, colic, diarrhea
Equine exfoliative eosinophilic dermatitis and stomatitis	Scaling and crusting that progress to generalized exfoliation, alopecia, ulceration, and exudation; variable pruritus	Severe progressive weight loss; no diarrhea, ravenous appetite
Equine cutaneous amyloidosis	Papules, nodules, and plaque over the head and neck that develop rapidly	Diffuse nodules in upper respiratory tract may cause severe dyspnea
ENDOCRINE DISEASES		

Hypothyroidism	Dull rough hair coat, delayed shedding of coat, edema of face and limb	Anecdotal reports of laminitis, infertility, anhidrosis, anemia, myopathy; weight gain and decreased food intake; skeletal limb disorders have been reported in foals
Hyperadrenocorticism	Long shaggy hair that fails to shed; mane and tail are unaffected	Polydipsia, polyuria, muscle wasting, weight loss, lethargy, swayback appearance, pendulous abdomen, blindness, chronic infections, neurologic disorders or signs
SWEAT GLAND DISORDERS		
Anhidrosis	Acute episode: none	Acute: labored breathing, fever, flared nostrils, lack of sweating, collapse, death
	Chronic: dry hair coat, excessive scaling, partial alopecia, pruritus	Chronic: polydipsia, polyuria, poor appetite, loss of body condition
MISCELLANEOUS DISEASES		
Panniculitis	Firm to fluctuant nodules most commonly found on trunk in subcutaneous tissue that ruptures and drains an oily yellow-brown to bloody discharge	Anorexia, depression, lethargy, pyrexia
NEOPLASTIC DISEASES		
Hemangioma and hemangiosarcoma	Two types: (1) well-circumscribed nodules that are blue-black in appearance; (2) dark hyperkeratotic and verrucous lesions that bleed easily	Anemia
Lymphosarcoma	Single or multiple dermal-to-subcutaneous nodules, especially on trunk	Internal organ involvement; usually fatal

12 CHAPTER 12 DISORDERS OF THE HEMATOPOIETIC SYSTEM

Debra C. Sellon

721

The hematopoietic system includes the blood and blood-forming tissues of the body. Peripheral blood cells are essential for tissue oxygenation, immune surveillance and clearance of foreign antigens, coagulation, and inflammatory reactions. Because of the interactions of blood with other body tissues and organs, alterations in blood parameters often reflect dysfunctions elsewhere in the body, and evaluation of the blood and its constituents has become an essential component of most diagnostic efforts.

This chapter discusses the basics of hematopoiesis and hematopoietic metabolism as they relate to specific disease conditions in the horse. Included is discussion of the erythron, leukon, platelets, and hemostatic mechanisms of the horse.

12.1 Erythron

Erythropoietic tissue of the bone marrow and the circulating erythrocytes often are referred to as the erythron, to emphasize their organlike function. Erythrocytes are essential for delivery of oxygen to all tissues of the body. The complex maturation and development of erythrocytes and their pivotal role in survival of all body tissues make them uniquely reflective of many pathologic conditions. An understanding of the erythron and its responses to perturbations in homeostatic mechanisms throughout the body can provide the astute clinician with invaluable clues in unraveling difficult diagnostic problems.

12.1.1 PHYSIOLOGY

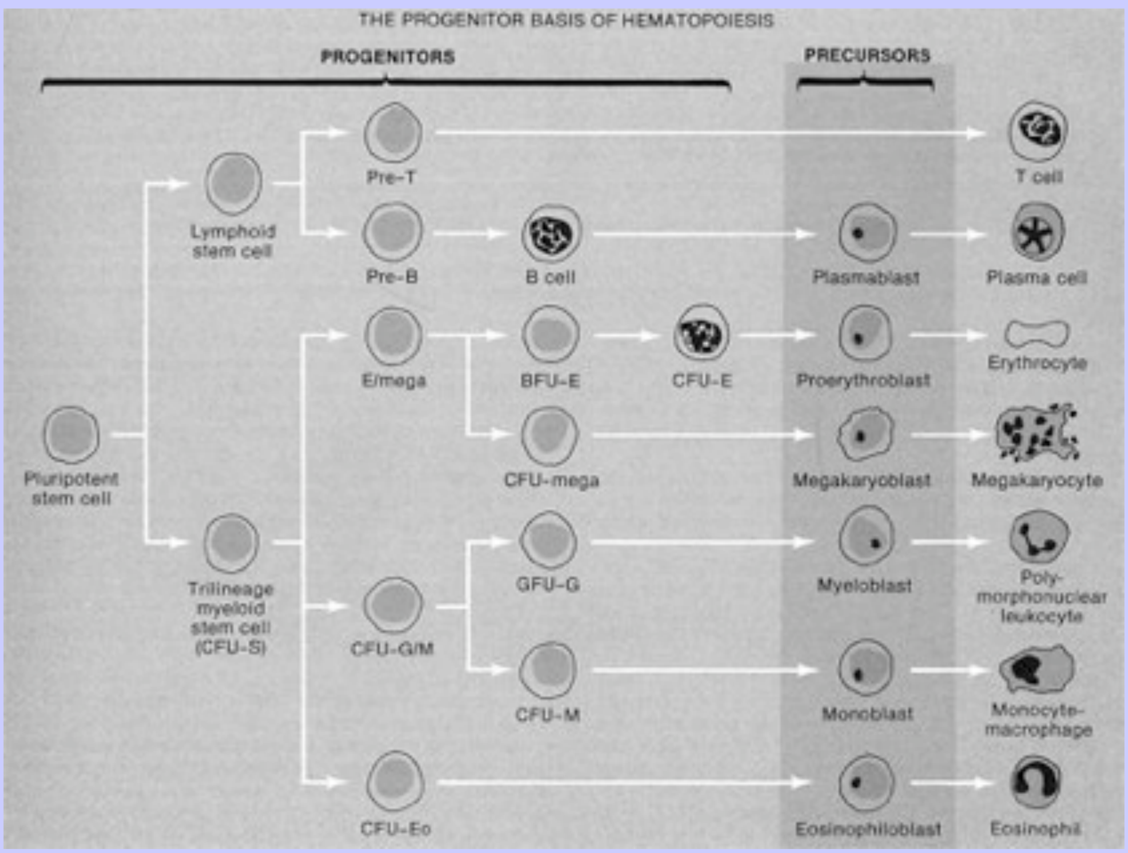
Erythropoiesis refers to the process of development and maturation of erythrocytes. Knowledge of the metabolic processes of these cells is critical to understanding pathologic processes that interfere with their primary function of tissue oxygenation.

In the fetus the cellular elements of blood are produced almost exclusively in the liver and spleen. As the body matures and differentiates in utero, hematopoiesis gradually shifts to the marrow cavities, so that at birth the bone marrow is the main organ of hematopoiesis. As an animal ages, bone marrow hematopoiesis decreases and fat infiltrates much of the previously active marrow. In the older adult animal, active hematopoiesis is limited to the marrow of the vertebrae, ribs, sternum, skull, and pelvis and the epiphyseal marrow of the humerus and femur.

Erythrocyte production begins from a pluripotent colony-forming unit stem cell capable of differentiating into erythroid-, myeloid-, megakaryocytoid-, or lymphoid-producing cell lines. The stem cell is capable of self-renewal to provide a continuing supply of pluripotent stem cells. The direction of differentiation is determined in part by the types and quantities of cytokine mediators to which the stem cell is exposed at the time it begins to divide. The exact combinations of mediators necessary to direct differentiation into each line are not understood entirely. In erythrocyte development the stem cell undergoes sequential mitotic divisions to produce the 721
committed erythrocyte progenitor burst-forming unit, followed by erythroid colony-forming units. These two 722
stages are capable of limited replicative self-renewal but are committed ultimately to differentiate into erythrocytes (Figure 12-1). Burst-promoting activity depends on the presence of various cytokines, including interleukin 3 (IL-3), IL-4, and granulocyte-macrophage colony-stimulating factor. The erythroid colony-forming

unit cell is the immediate precursor stage of the first morphologically recognizable erythrocyte precursor, the proerythroblast.

Figure 12-1 Schematic representation of the progenitor basis of hematopoiesis. Maturation is depicted from left to right with circulating blood cells as the final product on the far right of the drawing. Progressive amplification of progenitors and precursors as they mature and differentiate is not shown. *CFU-S,* Colony-forming unit–spleen; *CFU-G/M,* CFU–granulocyte macrophage; *CFU-Eo,* CFU–eosinophil; *BFU-E,* burst-forming unit, erythroid; *CFU-mega,* CFU–megakaryocyte; *CFU-G,* CFU–granulocyte; *CFU-M,* CFU–monocyte; *CFU-E,* CFU–erythrocyte. (From Nathan DG: Hematologic diseases. In Wyngaarden JB, Smith LH, editors: *Cecil textbook of medicine,* ed 18, Philadelphia, WB Saunders, 1988.)



Initial stages of erythrocyte development depend greatly on the presence of the glycoprotein hormone erythropoietin, which the kidney produces in response to renal hypoxia and is an absolute requirement for erythrocyte progenitor cell maturation and differentiation. The absence of erythropoietin, as in patients with

chronic renal disease, is associated with potentially severe nonregenerative anemia. Erythrocytosis, an increase in the circulating red blood cell (RBC) mass, is associated with excess secretion of erythropoietin in certain disease conditions.

Bone marrow proerythrocytes undergo four successive divisions followed by a period of maturation to produce 16 erythrocytes. Sequential divisions produce basophilic erythroblasts, polychromatophilic erythroblasts I and II, and orthochromic erythroblasts. The orthochromic erythroblast becomes a reticulocyte by ejecting its nucleus. 722
Reticulocyte production requires approximately 72 hours; 24 to 48 hours later the reticulocyte will have matured 723
into an erythrocyte. Iron is an essential component for hemoglobin synthesis and thus for erythropoiesis. The diet of the horse normally contains an abundance of readily available iron. Absorption is most efficient in the duodenum but may occur at almost any part of the gastrointestinal tract. The amount of iron absorbed from the gastrointestinal tract varies with the systemic iron status of the animal. Absorption increases in iron-depleted animals and decreases in animals with ample iron stores. Unabsorbed iron passes through the remainder of the tract and is lost in feces. Horses, especially young foals, supplemented with excessive dietary iron can develop hemochromatosis, hepatic cirrhosis, and liver failure.[1–4]

After absorption the blood transports iron complexed with the protein transferrin. In the liver, spleen, and bone marrow, iron is transferred to molecules of the storage protein ferritin. Approximately 30% of body iron is present in the storage proteins ferritin and hemosiderin (a complex aggregation of ferritin molecules). Only minute amounts of iron are complexed to the transport protein transferrin at any given time. Minor quantities of iron are also present in myoglobin and various electron transport molecules and enzymes. The hemoglobin of senescent erythrocytes removed from the peripheral circulation is degraded in cells of the mononuclear phagocyte system in the spleen, liver, and bone marrow. Iron ultimately is recycled to the bone marrow or liver to be used in synthesis of hemoglobin for new erythrocytes. Almost 70% of total body iron is present in hemoglobin.

Hemoglobin is synthesized in the mitochondria of the developing erythroblast and consists of four polypeptide chains (two α and two β in the adult) and a heme moiety. Heme is the functional portion of the hemoglobin molecule and contains an iron atom held in place by the four pyrrole rings of a porphyrin molecule. The iron in hemoglobin must be in the ferrous form (Fe^{2+}) to bind oxygen reversibly. Heme iron oxidized to the ferric form (Fe^{3+}) forms methemoglobin, and the molecule is no longer capable of transporting oxygen.

The normal life span of equine erythrocytes in circulation is approximately 150 days.[5,6] Mononuclear phagocytes of the spleen, liver, and bone marrow remove senescent RBCs from circulation. Transferrin transports released iron to RBC precursors in the marrow. Heme in phagocytic cells undergoes enzymatic degradation to biliverdin and then bilirubin. Phagocytic cells release unconjugated bilirubin into the circulation, where it binds to plasma albumin. Hepatocytes take up unconjugated bilirubin, which is conjugated and excreted via the bile into the gastrointestinal tract, where it is converted to urobilinogen and then stercobilin. Intravascular or extravascular hemolysis often results in increased serum unconjugated bilirubin concentrations.

During intravascular hemolysis, ruptured erythrocytes release heme, which combines with haptoglobin, an acute phase protein normally present in plasma, to be carried back to the liver, where heme is converted to bilirubin and excreted. If the level of haptoglobin exceeds the carrier capacity of the blood, the result is free hemoglobin in the plasma. Free plasma hemoglobin is filtered readily across the renal glomerulus and reabsorbed by renal tubular epithelial cells. Hemoglobin and other related pigment molecules, including myoglobin, are potentially nephrotoxic, and excessive intravascular hemolysis may result in acute renal failure.

The mature erythrocyte is an anucleate cell incapable of de novo protein synthesis to replace enzymes or other proteins that have been used during normal metabolism. Binding, transport, and delivery of oxygen to tissues does not require energy expenditure by the erythrocyte, but maintaining iron and various cellular proteins in a reduced state essential for proper function does require energy. Maintenance of appropriate electrolyte gradients across the RBC membrane also requires energy. Glucose is the main in vivo energy source for erythrocytes. RBCs differ from other cell types in the absence of the Krebs (tricarboxylic acid) cycle. Glucose must be metabolized via the anaerobic glycolytic (Embden-Meyerhof) pathway or via the hexose monophosphate shunt. The enzymes involved in these metabolic pathways are critical to RBC survival, and hereditary deficiencies described in other species are associated with severe anemia.

The body must maintain iron, hemoglobin, some critical RBC enzymes, and several membrane proteins in a reduced form for appropriate activity. High intracellular concentrations of glutathione (GSH), a sulfhydryl-containing tripeptide, are important for reduction of sulfhydryl groups of hemoglobin and other erythrocyte proteins. Reduction reactions involve the conversion of GSH to its oxidized form (GSSG), which then is returned to the reduced form (GSH) by the action of glutathione reductase. When the functional ferrous form of iron (Fe^{2+}) in hemoglobin is oxidized to the ferric form (Fe^{3+}), the resulting methemoglobin is incapable of carrying oxygen. Small amounts of methemoglobin (1% to 2% of total hemoglobin) are produced normally in erythrocytes. This methemoglobin is reduced to functional hemoglobin primarily via the action of the enzyme methemoglobin reductase.

12.1.2 EVALUATION OF THE ERYTHRON

Laboratory evaluation of the blood and bone marrow provides diagnostic clues that may aid the practitioner in diagnosing and treating a variety of disorders. Knowing the tests that are available and developing an 723
understanding of how and why they are performed aids one in interpreting the results. 724

TABLE 12-1 Reference Ranges for Equine Hematologic Parameters[*]

PARAMETER	UNITS	LIGHT HORSE[†]	DRAFT HORSE[‡]	MINIATURE HORSE[§]	DONKEY[||]
RBC count	$10^6/\mu l$	6.0–10.0	5.5–9.5	4.3–10.3	4.7–9.0
Hemoglobin	g/dl	12.0–17.0	8.0–14.0	9.0–16.0	9.5–16.5
PCV	%	32–50	24–44	24–42	28–47
MCV	fl	42–58	—	38–61	46–67
MCH	μg	15–20	—	14–23	16–23
MCHC	g/dl	32–38	—	33–40	32–36

RBC, Red blood cell; *PCV,* packed cell volume; *MCV,* mean corpuscular volume; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration.

* Numbers are for comparison only. Each laboratory should establish its own normal values.

12.1.2.1 Peripheral Blood Evaluation

Most clinical laboratories now use automated cell counters for evaluation of peripheral blood. These counters are capable of determining RBC counts, hemoglobin, packed cell volume (PCV), and various erythrocyte indices. Tables 12-1 and 12-2 list normal values for the horse.[7,8] These values are intended as guidelines only. Each laboratory should establish its own normal values for the horse.

RBC count, hemoglobin, and PCV are the most frequently used parameters for assessing the quantity of erythrocytes in circulation. In the normal horse, hemoglobin concentration is approximately one third of the PCV. This value increases in horses with intravascular hemolysis and hemoglobinemia. RBC count, hemoglobin concentration, and PCV decrease rapidly during the first weeks of life in the equine neonate. This decrease has been attributed to decreased erythrocyte production, a shorter RBC life span in the neonate, and hemodilution. During this period, mean RBC volume also decreases to the point that cells would be classified as microcytic if compared with normal adult values.[9]

TABLE 12-2 Influence of Breed on Normal Erythron Values (Mean Standard Deviation) in Adult Horses

BREED	RBC (×106/μl)[*]	Hgb (g/dl)	PCV (%)	MCV (fl)	MCH (pg)	MCHC (%)
Thoroughbred	9.35 ± 1.05	14.8 ± 1.3	41.7 ± 3.8	44.7 ± 3.4	15.9 ± 1.4	35.8 ± 1.4
Standardbred	8.37 ± 1.02	13.6 ± 1.6	38.3 ± 3.5	46.1 ± 4.0	16.3 ± 1.4	35.5 ± 1.6
Quarter Horse	8.26 ± 1.02	13.3 ± 1.6	38.0 ± 4.0	46.2 ± 3.9	16.1 ± 1.7	34.9 ± 1.6
Appaloosa	8.60 ± 1.11	13.3 ± 1.6	38.4 ± 4.7	44.8 ± 4.4	15.5 ± 1.3	34.5 ± 0.8
Arabian	8.41 ± 1.21	13.8 ± 2.1	39.3 ± 5.0	46.9 ± 1.9	16.4 ± 0.9	34.9 ± 1.0
Clydesdale	7.30 ± 0.87	12.4 ± 1.1	33.0 ± 3.0	44.6	—	38.1
Percheron	7.39 ± 1.08	11.7 ± 1.4	—	—	—	—
Mixed cold-blooded	7.76 ± 1.23	—	33.0 ± 7.0	42.3	—	—

* *RBC,* Red blood cell; *Hgb,* hemoglobin; *PCV,* packed cell volume; *MCV,* mean corpuscular volume; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration.

Evaluation of RBC indices can be helpful in characterizing anemia. If these parameters are not included in automated blood analyses, they may be calculated from the PCV, RBC count (in millions), and hemoglobin (in g/dl) as presented in Box 12-1.

Some automated cell counters also report RBC distribution width. This value may increase in some horses with anemia. Peripheral blood evaluation is not complete without a thorough examination of a stained blood smear to assess erythrocyte morphology. The normal equine erythrocyte is a biconcave disc, but in contrast to other species, most equine RBCs lack distinct central pallor. Equine RBCs normally exhibit a strong tendency 724
toward rouleau formation, a coinlike stacking or grouping of erythrocytes. This tendency causes equine 725
erythrocytes to sediment rapidly after collection, and one should mix all samples thoroughly immediately before any evaluation. Excellent pictures of normal and abnormal equine erythrocyte morphology are available in a variety of texts, and the reader is referred to those to aid in recognition of the following cell types[11,12]:

Poikilocyte: Any abnormally shaped erythrocyte. Poikilocytosis usually is reserved for description of RBCs that exhibit a variety of morphologies. If one particular shape predominates, one should use a more specific description.

Anisocytosis: A variability in the size of erythrocytes, usually associated with an increased RBC distribution width. Polychromasia indicates a variability in the color of erythrocytes usually caused by a variable hemoglobin and RNA content.

Spherocyte: Spherical erythrocyte in some horses with immune-mediated hemolysis.

Echinocyte: Burr cell with short, regularly spaced spicules projecting from the RBC surface. Echinocytes may be associated with uremia.

Acanthocyte: Spur cell with irregularly shaped spicules extending from the RBC surface. Acanthocytes may be associated with liver disease or gastrointestinal malabsorption.

Elliptocyte: Ellipsoid or oval erythrocyte found in animals with iron deficiency or myelophthisic anemia.

Leptocyte: Thin, flat RBC frequently associated with hepatic disease or iron deficiency.

Codocyte: Target cell with a dense central area of hemoglobin surrounded by a pale zone. Codocytes may be associated with hypochromic anemias or hepatic disease.

Howell-Jolly bodies: Basophilic nuclear remnants seen in the cytoplasm of erythrocytes. Approximately 10 in 10,000 erythrocytes contain Howell-Jolly bodies in the normal horse.[12]

Heinz bodies: Oxidized precipitated hemoglobin indicating oxidative damage to the RBC, usually resulting in intravascular or extravascular hemolysis. One may see Heinz bodies best using new methylene blue stain but may observe them in smears using Wright's stain as round structures protruding from the edge of the RBC membrane.

12.1.2.1.1

BOX 12-1 EVALUATION OF RED BLOOD CELL INDICES: CALCULATION FROM THE PACKED CELL VOLUME, RBC COUNT (IN MILLIONS), AND HEMOGLOBIN (IN g/dl)

$$\text{Mean corpuscular volume} = \frac{\text{Packed cell volume} \times 10}{\text{RBC count}}$$

Expressed as femtoliters (fl)

Increased in some horses with regenerative anemia

Decreased with iron deficiency anemia

Increased in older horses[10]

$$\text{Mean corpuscular hemoglobin} = \frac{\text{Hemoglobin} \times 10}{\text{RBC count}}$$

Expressed as picograms (pg)

Increased with intravascular hemolysis

Decreased with iron deficiency anemia

$$\text{Mean corpuscular hemoglobin concentration} = \frac{\text{Hemoglobin} \times 100}{\text{Packed cell volume}}$$

Expressed as grams per deciliter (g/dl)

Increased with intravascular hemolysis

Decreased with iron deficiency anemia

Occasionally, specialized tests of erythrocyte function or stability are indicated. Osmotic fragility tests measure the resistance of erythrocytes to in vitro hemolysis when incubated in increasingly hypotonic NaCl solutions. Erythrocytes from horses with immune-mediated hemolytic anemia frequently are more fragile than RBCs from normal horses.[13,14] The direct antiglobulin or Coombs' test is also helpful for diagnosing immune-mediated hemolytic anemia. Coombs' test detects immunoglobulin or complement on the surface of circulating erythrocytes. The Coombs' reagent should contain antisera to immunoglobulin G (IgG), IgM, and the third component of complement (C3). One incubates washed erythrocytes from the patient with Coombs' reagent and observes for agglutination. One may incubate cells at 10° C to detect cold reactive antibodies or at 30° C to detect warm reactive antibodies.[12] Because agglutination is the end point of the direct Coombs' test,

autoagglutination of blood is considered diagnostic of autoimmune hemolysis. One must differentiate autoagglutination from rouleau formation by dilution of an RBC suspension with isotonic saline. Saline disperses rouleau formation but does not affect true autoagglutination. The indirect Coombs' test detects the presence of circulating anti-RBC antibody in the serum by incubating patient serum with normal equine erythrocytes and monitoring for agglutination.

12.1.2.2 Bone Marrow Evaluation

Examination of the bone marrow of a horse is indicated if one identifies or suspects a disorder of the hematopoietic system but cannot diagnose it from information gathered by history, physical examination, and routine laboratory tests.[15] Bone marrow aspirates or core biopsies may be useful in characterizing anemias, 725
evaluating iron stores, or explaining quantitative or qualitative abnormalities of blood cells. 726

One may collect equine bone marrow aspirates or biopsies from the sternum,[15–17] tuber coxae, [15,18] or proximal ribs.[15,19] One obtains sternal aspirates from the ventral midline between the front legs. This site is preferable in most horses because hematopoietic activity persists throughout life, bones are not covered by a large muscle mass, and the marrow cavity is covered by only a thin layer of bone.[15] One may attempt an aspirate of the tuber coxae in young horses by directing the needle toward the opposite coxofemoral joint. One collects costal marrow from the proximal portion of an easily palpable cranial rib, usually beneath the latissimus dorsi and serratus posticus muscles.[19] One may use any large-gauge (16-gauge or larger) bone marrow needle with stylet to collect marrow aspirates. The needle should be at least 2 in long. The veterinarian clips the appropriate area and surgically scrubs it, injects a small amount of local anesthetic into the subcutaneous and periosteal tissues, and makes a stab incision through the skin and subcutaneous fascia. Forcing the bone marrow needle through the bone and into the marrow cavity may require considerable pressure and rotational movement.

The veterinarian removes the stylet from the needle; uses a sterile syringe containing a small quantity of anticoagulant to aspirate red-colored marrow, discontinuing aspiration when blood is visible in the hub of the syringe; withdraws the needle; and smears marrow from the hub of the syringe and the needle on glass microscope slides as for blood smears. Alternatively, one injects the marrow sample into a Petri dish. On visualization, one transfers spicules to a glass slide for staining. One may obtain core marrow biopsies using a 10-gauge Jamshidi needle and fixing the sample for routine histopathologic analysis.[15,20]

One should examine marrow samples first at low magnification for evidence of cellularity, distribution of fat cells, and heterogeneity of progenitor cell populations. At higher magnification, one may evaluate individual progenitor series and estimate a bone marrow myeloid to erythroid (M:E) ratio by counting 500 to 800 cells.[11] Descriptions and pictures of bone marrow progenitor cells are reported elsewhere, and the reader is referred to these for identification of cell types present in bone marrow aspirates or biopsies.[11,12,18] Normal M:E in the horse has been reported to range between 0.5 and 3.76.[16,17,19] Ratios of less than 0.5 are considered indicative of erythrocyte regeneration or myeloid suppression.[21] Special histochemical stains for iron (Prussian blue stain) are available to evaluate peripheral iron stores in the horse.[22] In many cases of hemolytic anemia, bone marrow macrophages may be visible with phagocytosed RBCs.

Myelophthisis is a reduction in the cellular elements in the bone marrow, frequently a result of myelofibrosis, proliferation of fibrous tissue in the marrow. Myelodysplasia implies accumulation of abnormal cells in the

bone marrow. These cells are often not dysplastic in the truest sense of the word but rather result from myeloproliferative neoplasia.

12.1.2.3 Iron Status Evaluation

Evaluation of systemic iron status is crucial to characterizing many hematologic abnormalities, especially in the investigation of anemias. Several laboratory parameters can aid in the identification and classification of abnormalities of iron metabolism. The peripheral blood smear may provide initial clues. Microcytic, hypochromic erythrocytes often are seen in animals with disturbances of iron metabolism. One may confirm these observations by calculating the mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) of peripheral blood erythrocytes. Measurement of serum ferritin provides a reliable index of stored hepatic and splenic iron in the horse. Serum ferritin concentration in 28 normal horses was 152 ± 54.6 ng/ml. A bone marrow aspirate examined after special iron stains is also an excellent means of assessing the pool of storage iron. Serum iron concentration reflects the total quantity of transport iron in the plasma (i.e., the quantity of iron bound to transferrin). Normal equine values of 120 ± 5.0 μg/dl[23] and 108 μg / dl[24] have been reported. The total iron-binding capacity (TIBC) reflects the amount of iron that plasma transferrin could bind if fully saturated. Normal TIBC in the horse has been reported as 388 ± 8.1 μg/dl.[23] One calculates the percentage of transferrin saturation from the serum iron concentration and the TIBC. Percentage transferrin saturation is normally approximately 30%. Serum iron concentration increases dramatically for 48 to 72 hours after administration of corticosteroids, but TIBC and serum ferritin concentrations do not.[25]

12.1.3 DISORDERS OF THE ERYTHRON

12.1.3.1 Erythrocytosis

Erythrocytosis or polycythemia is a real or apparent increase in the circulating RBC mass and may be classified as relative, caused by a decrease in plasma volume, or absolute, caused by a real increase in RBC numbers. Animals with persistent erythrocytosis have muddy red to blue mucous membranes, prolonged capillary refill time, weakness, lethargy, and exercise intolerance. Despite the large RBC mass in the circulation, oxygen delivery to the peripheral tissues often decreases because of increased blood viscosity and sludging in small vessels. Persistent erythrocytosis may lead to complications including hypertension, tissue hypoxia, thrombosis, and hemorrhage.[26] 726

727

12.1.3.1.1 Relative Erythrocytosis

Relative erythrocytosis or polycythemia may occur because of hemoconcentration or splenic contraction. Hemoconcentration occurs when total plasma volume decreases without any change in total RBC numbers in circulation. Clinical dehydration is usually evident, with slow capillary refill time, dry mucous membranes, and prolonged skin tenting. Dehydration may occur with excessive water losses accompanying diuresis, diarrhea, or excessive sweating or with decreased water intake. Endotoxic shock results in dehydration and hemoconcentration by causing a shift of water from plasma to the interstitial space. An increase in total plasma protein usually accompanies relative erythrocytosis caused by hemoconcentration. An exception to this occurs with concurrent loss of protein and body water (e.g., in horses with severe protein-losing diarrhea or glomerulonephritis). In these horses, total plasma protein may be normal or

decreased in the presence of a high PCV. The PCV of hemoconcentrated horses usually returns to normal after intravenous fluid therapy, unless water losses continue.

The spleen of the resting horse may harbor up to one third of the total circulating erythrocyte volume. Exercise, endogenous epinephrine release caused by excitement or stress, and exogenous epinephrine administration results in splenic contraction that may increase the PCV by as much as 50%.[27–30] This relative erythrocytosis is not accompanied by a significant increase in total plasma protein. If the horse is allowed to relax in a nonstressful environment, PCV usually returns to normal within a few hours.

12.1.3.1.2 Absolute Erythrocytosis

Absolute erythrocytosis occurs when increased erythropoiesis causes an increase in PCV, RBC count, and hemoglobin concentration. Plasma volume and plasma protein concentration remain normal.

Primary absolute erythrocytosis (including polycythemia vera) is rare and is considered a myeloproliferative disorder of the bone marrow.[26] Serum erythropoietin concentrations decrease to normal and Pao_2 is normal. This condition may be accompanied by thrombocytosis or leukocytosis. Severe erythrocytosis has been described in two horses with normal serum erythropoietin levels.[26,31]

Secondary absolute erythrocytosis may be appropriate or inappropriate, depending on the presence or absence, respectively, of tissue hypoxia. Appropriate secondary absolute erythrocytosis is associated with increased circulating erythropoietin levels caused by chronic hypoxia from right-to-left shunting of blood in the heart or great vessels, chronic pulmonary disease, or adaptation to high altitude. The most common cardiac anomalies associated with erythrocytosis are complex defects such as tetralogy or pentalogy of Fallot, although a number of other defects, including ventricular septal defect, eventually may result in right-to-left shunting and secondary erythrocytosis.[32] Horses with this condition frequently have cyanotic mucous membranes and an audible heart murmur. One can document chronic hypoxia by measuring the Pao_2. Oxygen saturation concentrations of less than 92% usually are required for stimulation of erythropoiesis.[26,33] One may confirm the diagnosis with cardiac radiography, ultrasonography, angiocardiography, or cardiac catheterization with blood gas and pressure analyses.

Erythrocytosis is rare in horses with chronic lung disease. Auscultation of animals with chronic lung disease severe enough to result in hypoxia likely would reveal abnormal lung sounds such as wheezes and crackles. Thoracic radiographs aid in assessing the extent and severity of the problem. One should direct treatment of these animals toward correction or alleviation of the primary problem. If this is not possible, periodic phlebotomy and removal of several liters of blood helps decrease blood viscosity and may improve the quality of life of these horses.

Inappropriate secondary absolute erythrocytosis occurs following increased erythropoietin or other hormone release in the absence of tissue hypoxia. Although reported in a horse with metastatic carcinoma,[34] this condition is most common in horses with hepatic neoplasms or renal abnormalities. These animals have a normal or nearly normal Pao_2. In human beings, hydronephrosis, renal cysts, and embryonal nephromata have been associated most frequently with this paraneoplastic syndrome. In the horse, secondary absolute erythrocytosis has been described along with hepatocellular carcinoma and hepatoblastoma. All affected horses have been less than 3 years of age, and concurrent elevations in serum erythropoietin and/or α-fetoprotein concentrations have been described.[35–37] These horses had a persistently elevated PCV that did not decrease with intravenous fluid therapy, normal plasma protein concentrations, and mild to moderate

elevations in hepatic enzymes. A horse with erythrocytosis following metastatic carcinoma also has been described.

Most horses with primary or secondary erythrocytosis have a guarded to poor prognosis. If an underlying disease exists, one should treat it appropriately. Intermittent phlebotomy may provide supportive therapy.[26]

12.1.3.2

Anemia

Anemia is a decrease in the circulating RBC mass caused by an imbalance in the rate of loss or destruction of erythrocytes and the rate of their production in the bone marrow. Anemia is not considered a primary diagnosis but rather a hematologic abnormality resulting from an underlying disease process. *Anemia* is defined most frequently as a decrease in PCV or RBC numbers. Hemoglobin also is decreased, except in cases 727
of intravascular hemolysis. A systematic approach to characterization of the anemia can provide valuable clues 728
in the diagnosis of an underlying disease process. All anemias may be classified as regenerative or nonregenerative based on bone marrow response to the decrease in circulating RBC mass. Regenerative anemia results from loss of intact erythrocytes from circulation (hemorrhage) or accelerated destruction of RBCs (hemolysis) and is characterized by an increase in effective erythropoiesis in the bone marrow. Nonregenerative anemia occurs following systemic abnormalities or because of intrinsic bone marrow disease and results from a lack of appropriate marrow erythropoiesis in response to normal or accelerated RBC senescence or destruction.

Anemia also may be characterized on the basis of erythrocyte size (MCV) and hemoglobin content (MCHC). Normocytic normochromic anemia accompanies many chronic systemic disease processes, including renal and hepatic failure, endocrine abnormalities, neoplastic conditions, and chronic infections. Microcytic hypochromic anemia (low MCV and MCHC) is associated classically with iron deficiency and megaloblastic anemia. Macrocytic anemia (increased MCV) occasionally occurs in horses after a severe hemolytic or hemorrhagic crisis.

Clinical signs of severe anemia relate to decreased tissue oxygenation and the physiologic compensatory mechanisms intended to alleviate this hypoxia. Signs include pallor of the mucous membranes, tachycardia, polypnea, weakness, lethargy, and a systolic heart murmur caused by decreased viscosity and increased turbulence of the blood as it flows through the heart and great vessels. Horses with mild to moderate anemia may have no obvious clinical signs or may have only lethargy and slightly pale mucous membranes. Other clinical signs, including fever, icterus, and hemoglobinuria, may be present in anemic horses and reflect the primary pathophysiologic process involved.

12.1.3.2.1

Regenerative Anemia

When erythrocytes are lost from the circulation at an accelerated rate by hemorrhage or hemolysis, the bone marrow responds by increasing its rate of erythrocyte production and release into the peripheral circulation. Documentation of an active regenerative response is important in diagnosis and prognosis of many cases of anemia. An increase in the number of reticulocytes in the peripheral circulation and an increase in the MCV are considered accurate indicators of a regenerative response in the bone marrow of most species. Unfortunately, in the horse, reticulocytes are not released into the peripheral circulation, even during a strong regenerative bone marrow response. Increases in MCV are inconsistent but slightly more common after hemolysis than after acute blood loss.[38–40] The only change in equine peripheral blood after acute

hemorrhage or hemolysis may be a slight anisocytosis that is quantitatively assessed through changes in RBC distribution width.[40–42]

Because of the difficulty in documenting a regenerative bone marrow response with conventional methods, several erythrocyte parameters have been investigated as markers of RBC regeneration in the equid.[43–45] Glucose-6-phosphate dehydrogenase, creatine,[43] and adenosine-5-triphosphate[46] increase in equine erythrocytes during a regenerative response, but tests for these are not available in most veterinary laboratories. The most practical, reliable method of assessing the erythrocyte regenerative response in an anemic horse is bone marrow analysis. A bone marrow M:E of less than 0.5 is considered evidence of erythrocyte regeneration.[21] Reticulocyte counts in the bone marrow are also indicative of a regenerative response in the horse. Normal equine bone marrow contains approximately 3% reticulocytes, but this may increase to as high as 66% in response to severe blood loss.[20,21]

12.1.3.2.1.1

Hemorrhage.

Blood loss anemia may develop acutely or chronically. In many cases the source of the hemorrhage is obvious, but in others is not. Internal hemorrhage (into body cavities) permits the body to reuse blood components. Approximately two thirds of the erythrocytes lost into the abdomen or thorax are autotransfused back into the circulation within 24 to 72 hours. The other one third are lysed or phagocytized and the iron and protein are reused. External hemorrhage (including hemorrhage into the gastrointestinal tract) prevents reuse of these components. Accelerated bone marrow erythropoiesis is usually evident by 3 days after acute hemorrhage and is maximal by 7 days.[11] Box 12-2 lists differential diagnoses for blood loss in the horse.

Clinical signs of hemorrhage in the horse vary depending on the duration and severity of blood loss. Horses may lose up to one third of their blood volume acutely without dying. Acute loss of large quantities of blood results in severe hypovolemic shock with tachycardia, polypnea, pale mucous membranes, poor venous distention, weakness, and oliguria. Initially, RBC parameters in the remaining circulating blood appear normal because all blood components have been lost in equal volumes. Physiologic compensatory mechanisms induce redistribution of interstitial fluid into the vasculature and eventually result in decreased RBC numbers and total protein in the peripheral blood. This redistribution may take up to 24 hours after acute hemorrhage. The difficulty in estimating the severity of blood loss during the first 24 hours after hemorrhage is compounded by the many erythrocytes that can be stored in the equine spleen and released into the circulation as a consequence of endogenous catecholamine release. After vascular equilibration, hematologic parameters should reveal a decrease in PCV, total RBC 728
count, and hemoglobin with no change in associated RBC indices (MCV, MCHC, and MCH). Anemia 729
caused by hemorrhage usually is accompanied by panhypoproteinemia because of significant loss of plasma proteins. A neutrophilic leukocytosis commonly is apparent by 3 hours after hemorrhage; platelets may increase as well if they have not been consumed by excessive coagulation.[11]

One may diagnose blood loss into the thoracic cavity by thoracic radiography, ultrasound, or thoracocentesis and may diagnose blood loss into the abdominal cavity by ultrasound or abdominocentesis. One may differentiate intraabdominal hemorrhage from inadvertent splenic aspiration or laceration of a subcutaneous blood vessel by the presence of erythrophacogytosis and absence of platelets and may differentiate recent hemorrhage into the abdominal cavity from diapedesis across compromised bowel or old hemorrhage by the presence of platelets in fresh blood. One may observe gastrointestinal blood loss as melena or hematochezia. More commonly, gastrointestinal hemorrhage is not severe enough to result in these overt signs, and feces appear normal. One may confirm a diagnosis by a simple and inexpensive fecal occult blood test.

Effective treatment of acute blood loss anemia must begin with finding and eliminating the source of hemorrhage. In many animals, this source is readily apparent, and direct pressure or surgical ligation of ruptured vessels is indicated. Internal hemorrhage is more difficult to control because immediate surgery to access the site of hemorrhage is usually not an option, as is most commonly the case in peripartum 729
hemorrhage of brood mares. Older mares[47–49] are at greatest risk for fatal hemorrhage because of rupture 730
of middle uterine, uteroovarian, or external iliac arteries.[49,50] A link between age and declining serum copper concentrations, vascular degeneration, and fatal hemorrhage has been proposed.[50] Therapy for mares with ruptured middle uterine artery is generally supportive with analgesics, sedatives to relieve anxiety and lower blood pressure, and oxytocin to enhance uterine involution. Blood transfusions, fluid therapy, hypertonic saline, and polymerized ultrapurified bovine hemoglobin have been administered to affected mares with variable success. However, volume expansion has the potential risk of exacerbating hemorrhage if one cannot achieve hemostasis.

In horses with acute severe hemorrhage the administration of isotonic crystalline intravenous fluids may aid tissue oxygenation by increasing peripheral blood volume and perfusion pressures. Administration of hypertonic saline solution (4 to 5 ml/kg of 7.5% NaCl) may be beneficial for rapid volume expansion after achieving adequate hemostasis.[51] Polymerized ultrapurified bovine hemoglobin is an alternative oxygen-carrying fluid that has been administered to horses in lieu of whole blood transfusion.[52,53] Although expensive, this product has the advantages of compatibility without crossmatching and long shelf life.

If 20% to 30% of the total blood volume is lost acutely, blood transfusion from a compatible donor horse is indicated. More detailed discussion of principles of blood and blood product therapy occur later in this

chapter. Hemorrhage into a large body cavity frequently is followed by autotransfusion of erythrocytes back into the peripheral circulation. Therefore one should not remove blood from these spaces unless necessary to stop continued bleeding, because the blood is interfering with vital organ function, or to lavage potentially septic sites.

Horses with subacute hemorrhage (over a few days) usually begin to show clinical signs of severe anemia when the PCV declines to 15% to 20%. The same clinical signs may not be noticeable in horses with chronic blood loss (over weeks to months) until the PCV reaches 12% or less. Because these laboratory parameters are so variable and potentially misleading, one should base treatment decisions on the clinical signs in the horse and not necessarily on the clinical laboratory parameters. A horse with subacute to chronic blood loss anemia severe enough to result in peripheral tissue anoxia because of inadequate RBC mass to supply needed oxygen exhibits tachycardia, polypnea, pale mucous membranes, weakness and lethargy, and possibly a mild to moderate systolic heart murmur caused by reduced viscosity and increased turbulence of the blood. If these signs are severe, blood transfusion is indicated. As with acute hemorrhage, one must identify the source of the blood loss. Other treatment is supportive and should be designed to eliminate the primary problem. If blood loss has occurred over weeks to months, body iron stores may be depleted, a particularly common problem with chronic gastrointestinal bleeding. Depletion of iron slows or stops effective bone marrow erythropoiesis so that these animals have laboratory parameters typical of iron deficiency anemia. One may identify low serum iron, low marrow iron stores, and increased TIBC, accompanying a hypochromic, microcytic anemia. One may supplement dietary iron orally with ferrous sulfate at a dose of 2 mg/kg body mass. One should not administer iron dextran parentally to horses because it has been associated with sudden death in this species. If one must administer iron intravenously, iron cacodylate solutions are available.

Because of the lack of peripheral signs of a bone marrow regenerative response in the horse, accurately assessing the regenerative efforts of bone marrow after hemorrhage may be difficult. One may evaluate serial bone marrow aspirates if this information is critical, but in most cases, monitoring increases in PCV over time is adequate. After experimental phlebotomy to mimic blood loss anemia in the horse, PCV increased about 0.672% per day, more slowly than in other species.[46] Experimentally, the bone marrow erythroid response peaked at 9 days after phlebotomy, coinciding with the lowest marrow M:E. Regeneration of the erythroid compartment was incomplete 31 days after hemorrhage.[54]

12.1.3.2.1.2 Hemolysis.

Intravascular or extravascular destruction of erythrocytes can occur in a variety of disorders. During intravascular hemolysis, hemoglobin released from destroyed erythrocytes combines with plasma haptoglobin, and tissue mononuclear phagocytes remove the haptoglobin-hemoglobin complex. Plasma haptoglobin levels decrease as intravascular hemolysis increases.[55,56] When plasma haptoglobin binding is exceeded, free hemoglobin accumulates in the plasma and is eliminated via the kidneys. Thus the hallmarks of intravascular hemolysis are hemoglobinemia and hemoglobinuria. Horses recovering from a severe hemolytic episode are more likely to have a demonstrable increase in MCV than are horses recovering from acute blood loss.[38,39,57]

Acute hemolytic anemia of adult horses has been associated with a variety of pathologic conditions (Box 12-3). Dimethyl sulfoxide administered intravenously at concentrations of 50% or greater results in severe intravascular hemolysis.[58] Hemolytic-uremic syndrome is characterized by acute renal failure, microangiopathic hemolytic anemia, and intravascular coagulation. Erythrocytes become damaged as

they pass between fibrin strands deposited in the lumen of small renal vessels. Thrombocytopenia may occur concurrently.[59,60] Hemolysis has been reported in horses ingesting leaves of the northern red oak (*Quercus rubra* L. var. *borealis*). Other associated clinical signs included abdominal pain, constipation, and increased coagulation times.[61] Administration of significantly hypotonic or hypertonic solutions to horses also may result in intravascular hemolysis.[51] All these conditions are uncommon in the horse. The most common causes of hemolysis are immune-mediated disease, oxidant-induced damage to erythrocytes, and infectious diseases.

12.1.3.2.1.2.2

Immune-Mediated Hemolytic Anemia (IMHA).

IMHA develops when an animal produces antibodies that attach to the surface of RBCs. Primary IMHA is an autoimmune process in which antibodies are directed against surface antigens and occurs when a normally suppressed B lymphocyte clone proliferates and produces an antibody directed against normal RBCs.[62] Secondary IMHA is more common than true autoimmune disease. Antibodies attach to the surface of erythrocytes for one or more reason: (1) alterations in the RBC membrane produced by a primary viral, bacterial, or neoplastic disease process; (2) antigen-antibody complex deposition on the surface of RBCs; or (3) drugs that cause immunoproteins to react indirectly with RBCs.

Drug-induced immune-mediated hemolysis may occur via three mechanisms[63]:

1. The drug may combine with RBC membranes and may be recognized as foreign by the body. An antibody to this new antigen develops and destroys the drug-coated erythrocytes. These animals have a positive direct Coombs' test.

2. The drug may complex with a carrier molecule in the blood and induce an immune response, and the drug-carrier-antibody complex attaches to RBC membranes in a complement-mediated process that leads to hemolysis.

3. Occasionally, a drug may induce true autoantibody production that leads to RBC destruction.

Antibody-coated RBCs are unable to pass through the microcirculation of the spleen, become sequestered there, and are destroyed or phagocytized. If RBC membrane is lost in excess of intracellular contents, spherocytes with an increased osmotic fragility form. Most immune-mediated hemolysis is extravascular, but if the antibody fixes and activates complement, intravascular complement-mediated hemolysis may result.[12]

IMHA may be classified as warm or cold hemagglutinin disease based on the optimal temperature at which the autoantibody agglutinates the host RBCs. Many clinical pathologists believe that these designations can be arbitrary and reflect an in vitro phenomenon rather than in vivo pathogenesis. Classically, in cold hemagglutinin disease the antibody involved is IgM. Complement is activated, and the liver is the primary site of removal of injured RBCs from the circulation. In warm hemagglutinin disease, IgG more commonly is involved, and the spleen is the primary site of RBC sequestration.[12,64,65] Warm hemagglutinins are frequently incomplete (i.e., they do not cause autoagglutination).[64] Warm[66,67] and cold[64,68] hemagglutinin anemia have been described in the horse.

Primary and secondary IMHA are uncommon in the adult horse.[42] Onset of disease is usually insidious, and many horses have fever, lethargy, and weight loss or have signs referable to a primary disease process. Routine hematologic and biochemical analyses frequently reveal decreased RBC 731 numbers, spherocytosis, increased MCV, 732 anisocytosis, and an increased total and indirect bilirubin. Most cases of immune-mediated hemolysis involve extravascular RBC destruction, but if intravascular hemolysis is occurring, hemoglobinuria will occur. One confirms the diagnosis by documenting a regenerative erythropoietic response in the bone marrow, increased erythrocyte fragility in hypotonic saline, autoagglutination, and a positive direct antiglobulin or Coombs' test. The Coombs' reagent used should contain antisera to IgG, IgM, and C3. One must differentiate autoagglutination from rouleau formation by dilution of a cell suspension with isotonic saline. Saline disperses rouleau formation but does not affect true autoagglutination.

In human beings, IMHA has been associated with lymphoreticular neoplasms, a variety of viral and bacterial diseases, inflammatory or granulomatous diseases, and generalized autoimmune disorders such as systemic lupus erythematosus. One may have difficulty distinguishing between primary AIHA, in which autoantibodies are directed against an abnormal epitope on the erythrocyte membrane, and nonspecific immune complex deposition on the surface of erythrocytes, usually occurring via attachment to Fc or complement receptors. In the horse, immune-mediated hemolysis has been reported in association with *Clostridium perfringens* septicemia,[42,65] an unclassified respiratory infection,[42] purpura hemorrhagica,[68,69] a streptococcal abscess,[68] and lymphosarcoma.[13,68,69] Regardless of the exact sequence of events leading to antibody deposition on the surface of erythrocytes, affected horses show clinical signs similar to those described for primary AIHA, and clinical pathologic data and diagnosis are similar.

IMHA after treatment with penicillin has been documented in horses.[70–73] Most affected horses have not been hemoglobinuric, indicating predominantly extravascular hemolysis. IMHA in the horse also

has been associated with administration of trimethoprim-sulfamethoxazole.[74] Although not documented as causing immune-mediated hemolysis in the horse, drugs that have caused this problem in other species include tetracycline, rifampin, cephalosporins, chlorpromazine, and various nonsteroidal antiinflammatory drugs (NSAIDs). In all reported cases of drug-induced IMHA in horses, the problem has resolved with discontinuation of administration of the offending therapeutic agent and appropriate supportive care.

Neonatal isoerythrolysis is an important form of immune-mediated hemolysis in the foal[75] and is discussed in detail elsewhere in this text.

Immune-mediated anemia resulting in intravascular and extravascular hemolysis may be present in horses with equine infectious anemia (see the following discussion). Infected horses may have a positive result on the Coombs' test or exhibit autoagglutination, especially during acute disease. Immune-mediated anemia also has been described in a horse with systemic lupus erythrematosus.[76]

Therapy of immune-mediated hemolysis is similar regardless of the initiating factor(s) involved. One should discontinue any previously administered drug and treat specifically underlying primary disease processes. If hemolysis is severe and life-threatening, the veterinarian should administer blood transfusions from a compatible donor (see the discussion on blood transfusion). If the horse has severe intravascular hemolysis with hemoglobinuria, one should initiate intravenous fluid therapy to protect against pigment-induced nephropathy.

Several cases of immune-mediated hemolysis in the horse have been at least transiently responsive to corticosteroid therapy.[13,42,66] One horse experienced complete disease remission after a 10-week regimen of glucocorticoids.[62] Parenterally administered corticosteroids are recommended initially, and dexamethasone is probably the drug of choice. One should titrate the amount and frequency of administration to the response of the individual animal, but one may try an initial dose of 20 to 30 mg dexamethasone in an adult horse. Ideally, administration of corticosteroids in the morning minimizes interference with the circadian rhythm of endogenous corticosteroid release from the adrenal gland. However, in an acute hemolytic crisis, twice daily administration of dexamethasone is recommended until RBC numbers cease to decline. After stabilization, one should decrease corticosteroid doses to once daily, then every other day, and gradually discontinue the therapy. If the horse requires long-term therapy, one may administer prednisolone orally with a declining every-other-day dosage. Potential complications of corticosteroid therapy in the horse include laminitis and secondary infections. Exacerbation of primary infectious conditions also may occur in cases of secondary autoimmune hemolysis treated with corticosteroids. Caution is recommended, especially when using corticosteroids at a high dose or for a prolonged period. One horse with IMHA refractory to corticosteroid therapy was treated successfully with cyclophosphamide at 1.1 mg/kg intramuscularly once daily and azathioprine at 1.1 mg/kg intramuscularly once daily.[77]

Oxidative injury to RBCs is evident from Heinz body formation, hemolytic anemia, and methemoglobinemia. Heinz bodies are aggregations of oxidized precipitated hemoglobin. They are small, round, blue-black, refractile granules near the cellular margin of erythrocytes stained with new methylene blue.[78] Heinz bodies damage the erythrocyte membrane, disturbing intracellular tonicity and resulting in rupture of the cell (intravascular hemolysis). Cells of the mononuclear/phagocyte system of the spleen and liver may take less damaged RBC membranes as abnormal and remove the RBCs from the peripheral circulation (extravascular hemolysis).

Oxidation of iron in the hemoglobin molecule from the normal ferrous state (Fe^{2+}) to the ferric state (Fe^{3+}) forms methemoglobin. Erythrocytes normally produce methemoglobin, which cellular enzymes rapidly convert back to hemoglobin. Also, cellular GSH acts to decrease the amount of methemoglobin formed by competing with hemoglobin for oxidizing agents.[79] Methemoglobin is incapable of carrying oxygen, and excessive accumulation results in a brownish discoloration of blood. Methemoglobin formation alone does not result in hemolysis,[80] but toxins simultaneously may oxidize the sulfhydryl groups of the globin moiety of methemoglobin. This oxidation causes methemoglobin denaturation and precipitation, Heinz body formation, and intravascular hemolysis. Pathologic methemoglobin accumulation in the blood most frequently results from exposure to an oxidative toxin that overwhelms the protective mechanisms of the body but also may result from a decreased rate of reduction of physiologically produced methemoglobin. Familial methemoglobinemia and hemolytic anemia caused by decreased erythrocyte GSH reductase and intracellular GSH have been described in two Trotter mares.[81]

Acute hemolytic anemia and methemoglobinemia can develop in horses after ingestion of wilted red maple *(Acer rubrum)* leaves.[57,82–84] Freshly harvested leaves are not dangerous but become toxic when dried and remain so for at least 30 days. Overnight freezing of the leaves does not affect toxicity. Affected horses may experience brownish discoloration of the blood (massive methemoglobinemia) and peracute death within 12 to 18 hours of exposure. A more prolonged hemolytic syndrome characterized by icterus, methemoglobinemia, hemoglobinuria, bilirubinemia, bilirubinuria, and possibly death may occur 5 days or more after ingestion of wilted leaves. Laboratory evaluation of horses with the hemolytic syndrome of red maple leaf toxicosis frequently reveals Heinz body anemia, depletion of RBC-reduced GSH, and increased RBC osmotic fragility.[83] Normal methemoglobin concentration in equine blood is 1.77% of total hemoglobin.[81] Horses with red maple leaf toxicosis may have methemoglobin concentrations of close to 50% of total hemoglobin.[84]

Treatment of horses with red maple leaf toxicity includes eliminating access to the toxic leaves, whole blood or packed cell transfusions as needed, and general nursing care. The veterinarian should treat all exposed animals with activated charcoal via nasogastric tube to decrease absorption of toxin, even if several days have elapsed since exposure. Massive intravascular hemolysis may result in pigment-induced nephropathy. Fluid diuresis is indicated to prevent or treat this complication. One should use potentially nephrotoxic drugs with caution. Some clinicians have suggested dexamethasone administration to stabilize cellular membranes.[82,85] Methylene blue therapy has been attempted in some horses without success.[57] Because methylene blue may potentiate hemolysis, its use is not advisable. Two horses with severe hemolysis and methemoglobinemia caused by ingestion of red maple leaves were treated with large doses of ascorbic acid (vitamin C).[85] Ascorbic acid is thought to convert methemoglobin to reduced hemoglobin and may supplement endogenous protective mechanisms.[86] One may give adult horses a dose of ascorbic acid at 30 mg/kg twice daily in intravenous fluids.[85]

Prognosis for horses with red maple leaf toxicosis is guarded to poor and is not correlated with PCV or methemoglobin concentration at the time of presentation. Horses are at risk for pigment nephropathy and acute anuric renal failure, colic, diarrhea, and laminitis.[84]

Outbreaks of Heinz body anemia have been reported in horses with access to unharvested onions[87] or overgrazed pasture covered with wild onions *(Allium canadense)*.[78] The toxic principle in onions is *n*-propyl disulfide. Treatment should include removal from access to the plants, activated charcoal via nasogastric tube to reduce absorption of the toxin, and blood transfusions and supportive care as indicated.

Heinz body anemia in horses also has been reported after phenothiazine administration. Toxicity appears to depend on individual susceptibility and some as yet unidentified environmental factors. Groups of animals may be affected at a dose that is generally considered safe, and animals in poor condition may be more susceptible to toxicity.[88] Although a 30-g dose for a 1000-lb horse is considered safe, one report described poisoning in six of nine horses treated with 25 g of phenothiazine.[89] Because phenothiazine is no longer widely used as an equine anthelmintic, reports of its toxicity are becoming rare.

Nitrate poisoning is associated with methemoglobin formation in horses but only rarely with intravascular hemolysis. The horse is believed to be more susceptible to nitrate poisoning than other simple-stomach species because the cecum and colon provide an optimal environment for microbial reduction of nitrate to nitrite.[57,90,91] Decreases in methemoglobin concentration have been reported after administration of methylene blue to horses with experimentally induced nitrate poisoning.[57]

Heinz body anemia has been reported in one horse with lymphosarcoma.[92] The authors could not confirm access to known oxidative toxins and presumed the anemia to be caused by the neoplastic process by an unidentified mechanism.

Equine infectious anemia virus (EIAV) is a viral disease of horses known colloquially in the United States as swamp fever because of its high prevalence in Gulf Coast states where climatic conditions are 733
favorable for transmission. The causative agent is a member of the lentivirus genus of the family 734
Retroviridae. Infected horses may have one of three clinical syndromes: acute infection, chronic infection, or inapparent carrier.[93,94]

Acutely infected horses show fever, lethargy, and anorexia within 30 days of exposure. The most consistent hematologic abnormality in these horses is thrombocytopenia, although anemia also may be present. Many acutely infected animals show few if any recognizable clinical signs, and definitive diagnosis may be difficult because some of these horses are not yet seropositive. Most horses seroconvert by 40 days after infection.

The horse chronically infected with EIAV has classic signs of recurrent fever, weight loss, ventral edema, and anemia. These animals are seropositive by the agar gel immunodiffusion (AGID or Coggins) test or by competitive enzyme-linked immunosorbent assay (C-ELISA). Each cycle of disease is associated with the emergence of a new antigenic strain of the virus, temporary evasion of the host immune response, and replication of the virus to high titer.

The anemia from which the disease derives its name results from intravascular and extravascular hemolysis of complement-coated RBCs and an impaired bone marrow response.[95–98] Each febrile episode is associated with thrombocytopenia, but platelet counts rebound rapidly as temperature

returns to normal. Thrombocytopenia may result from immune[99] or nonimmune[100] platelet destruction or decreased platelet production in the bone marrow.[101]

Most EIAV seropositive horses are clinically normal and never show any recognizable clinical signs. However, they have immune-related blood abnormalities (hyperglobulinemia, decreased percentage of $CD5^+$ and $CD4^+$ lymphocytes) consistent with ongoing viral activity.[102] These animals are inapparent carriers of the virus and remain infected for life. They have circulating infectious virus in their blood and remain a threat to other horses for the rest of their lives. Regardless of disease stage (acute, chronic, or inapparent carrier), virus is found in vivo primarily in tissue macrophages and endothelial cells.[103–105]

Transmission of EIAV occurs predominantly by the intermittent feeding of hematophagous insects such as horseflies and deerflies. Flies are strictly mechanical vectors, and virus does not appear to survive more than 30 minutes on their mouthparts. Chances of transmission are greatest when flies feed on horses undergoing a febrile, viremic episode. However, horseflies can transmit virus from inapparent carrier horses to uninfected animals under field conditions, so all seropositive horses must be considered infectious for life.

EIAV also can be transmitted iatrogenically with blood product transfusions and previously used or improperly sterilized needles, surgical instruments, tattooing instruments, dental equipment, or any other blood-contaminated materials. Virus occasionally is transmitted across the placental barrier from an infected mare to her foal. Mares experiencing a febrile episode during gestation are more likely to give birth to infected foals than are asymptomatic mares. Of foals born to chronic carrier mares, approximately 10% are virus and antibody positive.[106,107] Virus transmission to foals may occur by ingestion of colostrum and milk from infected mares.[107,108] Foals born to antibody-positive mares usually are seropositive for EIAV at 24 hours of age because of absorption of colostral immunoglobulins. This colostral immunity is usually undetectable by 6 months of age.[107,108]

The Coggins test and C-ELISA are recognized by the U.S. Department of Agriculture as valid and reliable for the diagnosis of EIAV. Good correlation has been reported between Coggins test results and C-ELISA results.[109] A few horses have been identified, however, with consistently negative or equivocal AGID results that were proved subsequently to be infected.[110,111]

No specific antiviral therapy for EIAV is available. Treatment of an animal requires supportive therapy as indicated during febrile episodes. Minimizing environmental stress may be helpful in decreasing the severity and recurrence of clinical signs. Intrastate travel of infected horses is regulated by state laws. Most state controls include options of euthanasia, some form of permanent identification with a 200-yard quarantine for the life of the horse, or shipping the animal to a recognized research facility.

Federal law prohibits interstate travel of horses that have tested positive for EIAV. Interstate movement of infected horses is allowed under three conditions: (1) back to the farm of origin; (2) to slaughter; and (3) to a diagnostic laboratory or approved research facility. Before interstate movement, reactors must be identified officially using the national uniform tag code number assigned by the U.S. Department of Agriculture to the state in which the reactor was tested, followed by the letter *A*. A hot iron, chemical brand, or freeze-marking may be used. Markings must be at least 2 inches high and applied to the left shoulder or left side of the neck. Lip tattoos should not be less than 1 inch high and ¾ inch wide and should be applied to the inner surface of the upper lip of the reactor. Veterinarians

who falsify health certificates of EIAV reactors may be reprimanded, fined up to $1,000, or lose their federal accreditation.[112]

Despite the significant decline in the incidence of EIAV in the United States since these control measures were implemented in the mid-1970s, propagating epizootics still occur.[113] Veterinarians should advise horse owners to do the following:

1. Require a negative EIAV test as part of every prepurchase examination. 734

735

2. Require all new arrivals on a farm to have documentation of a recent negative EIAV test, and test all horses on the farm yearly.
3. Practice excellent fly control.
4. Encourage all events involving the congregation of horses to require documentation of a recent negative EIAV test.
5. Thoroughly disinfect any surgical items contacting equine blood before use on another horse.

Equine piroplasmosis results from infection with one or both of two species of hemoprotozoan parasite: *Babesia caballi* and *B. equi*. These intraerythrocytic parasites are found in subtropical locales and transmitted predominantly by tick vectors. Although classified in the genus *Babesia, B. equi* may be related more closely to the theilerial organisms.[114] *B. equi* undergoes some developmental stages in lymphocytes and apparently lacks transovarial tick transmission typical of most *Babesia* organisms.

Piroplasmosis is only enzootic in those areas where the tick vector can survive the winter. *B. caballi* infection has been diagnosed in horses in Florida and is spread by the tropical horse tick *Dermacentor nitens*. In the United States, *D. nitens* is found in southeastern Florida and occasionally in Texas. Only rarely has *B. equi* infection been confirmed in horses in the United States, and none of the ticks commonly found in this country are known to transmit this organism. Horses raised in *Babesia*-endemic areas frequently are infected with the organism(s) without ever showing recognizable clinical signs. Clinically recovered horses remain infected asymptomatic carriers of the organism as well, and stress may precipitate clinical relapse. Horses with *B. caballi* infection may clear the organism spontaneously after 12 to 42 months, whereas *B. equi*–infected horses do not appear to clear the organism spontaneously.[115] Infected animals develop a strong active immunity that depends on the continuing presence of the organism (premunity). They may be reinfected readily soon after the organism is eliminated from the body. No evidence of cross-protection exists between the two species of *Babesia*.[116]

Previously unexposed adult horses develop clinical signs of disease within 1 to 4 weeks of exposure. The horse may have fever, depression, dyspnea, pale or icteric mucous membranes, ecchymoses of the nictitating membrane, constipation, colic, and dependent edema. As anemia worsens, affected horses may develop diarrhea. Massive intravascular destruction of parasitized erythrocytes occasionally occurs, resulting in hemoglobinuria. Clinical disease with *B. caballi* lasts a few days to a few weeks, and mortality is usually low. Horses infected with *B. equi* generally have a more severe clinical course and may die within 24 to 48 hours of initial signs. Confirmation of diagnosis is by identification of the *Babesia* organism in blood smears stained with a Giemsa-type stain or by complement fixation test. The absence of *Babesia* organisms in the peripheral blood does not exclude the diagnosis of

piroplasmosis because parasitemia may be brief and occur before the onset of recognizable clinical signs.

Treatment of piroplasmosis varies depending on the location of the horse and the desired goal of treatment. In animals that reside in *Babesia*-endemic areas, suppressing clinical signs without eliminating the organism from the body is desirable, because premunition depends on the continued presence of the parasite at low levels. Clinical signs usually subside after one intramuscular injection of imidocarb dipropionate (Burroughs Wellcome Co., Research Triangle Park, North Carolina) at 2.2 mg/kg. Owners who wish to move their horses to or enter *Babesia*- free areas should isolate them from all tick vectors and should have them treated to eliminate the organism. *B. caballi* usually is eliminated after administration of imidocarb dipropionate at 2 mg/kg intramuscularly once daily for 2 days.[117] *B. equi* is a more difficult organism to eliminate from the horse, and four doses of imidocarb at 4 mg/kg intramuscularly at 72-hour intervals had variable efficacy in eliminating the carrier state.[118–120] In one study by Frerichs, Allen, and Holbrook,[119] the foregoing treatment regimen successfully cleared 13 of 14 horses of the infection, whereas in a more recent study by Kuttler, Zaugg, and Gipson, this treatment regimen cleared none of nine geldings of infection. This wide difference in efficacy may be because of strain differences in drug susceptibility.[118] Potential adverse effects of imidocarb administration include salivation, restlessness, colic, and gastrointestinal tract hypermotility. Donkeys appear to be sensitive to the toxic effects of imidocarb, and eight donkeys treated with the drug died.[119] Although the antitheilerial drug buparvaquone at 4 to 6 mg/kg intravenously or intramuscularly is therapeutically effective in horses acutely infected with *B. equi,* it is not consistent in clearing infection in carrier horses.[121]

12.1.3.2.1.2.3

Severe Hepatic Disease.

Acute intravascular hemolysis and anemia may develop in the terminal stages of acute or chronic hepatic failure in horses and is characterized by hemoglobinemia, hemoglobinuria, and icterus.[122] Onset and progression are rapid, and the condition is usually fatal. Affected erythrocytes have increased osmotic fragility. Hemolysis may result from decreased structural integrity of the erythrocyte membrane caused by alterations in exchangeable RBC membrane lipoproteins and the effect of bile acids on erythrocyte metabolism during liver failure.[12]

12.1.3.2.1.2.4

Microangiopathic Hemolysis.

This disorder occurs following thrombosis or fibrinoid change within the lumen of small blood vessels, 735
[123] is typical of chronic disseminated intravascular coagulation, and has been reported in horses.[59] The 736
resulting hemolyis is usually mild.

12.1.3.2.2

Nonregenerative Anemia

A variety of intrinsic or extrinsic factors may suppress normal bone marrow erythropoiesis, resulting in anemia caused by a failure to replace senescent RBCs adequately as they are removed from circulation (Box 12-4). Dietary factors often are incriminated in these abnormalities but only rarely are involved. Severe protein deprivation may result in decreased erythropoiesis as the body becomes deficient in synthesizing hemoglobin and other cellular proteins. Folic acid and cobalamin (vitamin B_{12}) deficiencies are known to

cause macrocytic hypochromic anemia in human beings, but they are associated rarely with anemia in domestic animals, including the horse. Horses do not have an absolute dietary requirement for vitamin B_{12}, which is produced by bacterial action in the gut and absorbed from the lower gastrointestinal tract.[124] Anemia associated with hypothyroidism is thought to be functional, following a lowered metabolic rate. Normocytic normochromic anemia responsive only to thyroid replacement therapy has been reported in one horse.[125] The most common disorders associated with nonregenerative anemia in the horse are iron deficiency, chronic inflammatory, endocrine, or neoplastic diseases, and generalized bone marrow failure.

Miscellaneous Conditions

Administration of human recombinant erythropoietin

Chronic hepatic disease

Chronic renal diseae

Recent hemorrhage or hemolysis

12.1.3.2.2.2

Iron Deficiency.

Iron deficiency in the horse is associated only rarely with low dietary iron intake or absorption. Instead, iron deficiency results from chronic external blood loss. Iron deficiency can be divided into three stages, each of which varies in its laboratory abnormalities. Initially, the only detectable abnormalities reflect decreased iron storage pools: a low serum ferritin concentration and decreased stainable iron in the bone marrow. Progression of the condition affects erythropoiesis adversely. These animals have a decrease in the percentage saturation of plasma transferrin, an increased TIBC, and increased numbers of hypochromic erythrocytes (decreased MCHC). Fulminant iron deficiency anemia leads to abnormal development of erythrocytes in the bone marrow late in the maturation process. Cells continue to divide in the late rubricyte stage, without sufficient iron to continue heme synthesis. The result is the release of small cells with decreased hemoglobin concentration into the peripheral circulation (decreased MCHC and MCV).

Treatment of iron deficiency anemia should concentrate initially on the identification and elimination of the source of chronic iron loss. In the horse, occult blood loss occurs most frequently from the gastrointestinal tract and may be verified with a fecal occult blood test. Chronic gastrointestinal ulceration following phenylbutazone administration is a well-recognized phenomenon and is more frequent and severe in ponies than in horses. Gastrointestinal parasites, especially *Strongylus vulgaris* and small strongyles, occasionally may result in chronic blood loss and subsequent iron deficiency. Many iron-containing hematinics are available commercially, and oral supplementation with a product containing ferrous sulfate is probably best. Parenteral iron dextran solutions have been associated with fatal anaphylactoid reactions in horses. If parenteral administration is essential, 1 g of iron cacodylate administered intravenously for an adult horse generally is considered safe.

Serum ferritin concentration increases, and TIBC decreases over the first 24 hours of life in foals. Because serum iron concentrations and percentage saturation of transferrin are high during this period, oral iron supplementation is contraindicated within the first 2 days of life.[9,126] Administration of oral digestive inoculants containing ferrous fumarate to neonatal foals has been associated with a fatal toxic hepatopathy characterized by icterus, hepatic atrophy, bile duct hyperplasia, lobular necrosis, and intrahepatic cholestasis.[2,127]

736

Over the next few weeks of life, serum ferritin decreases and then increases to normal adult values by 6 months of age. These ferritin changes occur concomitantly with opposite changes in serum TIBC, and together with a low MCV may indicate a functional iron deficiency in the foal.[126] Tissue demands for iron are high during periods of active growth, and foals may be more susceptible than adults to the development of iron deficiency anemia. In a survey of iron status in hospitalized horses, only six animals with iron deficiency were identified on the basis of low serum ferritin and serum iron concentrations. All six were foals younger than 5 weeks of age.[128] This hypothesis of marginal iron status during early life has been disputed by other researchers who saw no beneficial effect on hematologic variables when giving foals iron supplementation orally.[129]

12.1.3.2.2.3

Chronic Disease.

Chronic inflammatory conditions and neoplasms frequently are associated with a mild to moderate normocytic, normochromic, nonregenerative anemia. This anemia has been attributed to several abnormalities. A block of iron release from reticuloendothelial storage (ferritin and hemosiderin) results in an unavailability of iron for heme synthesis. One may confirm and differentiate defective iron metabolism from iron deficiency anemia by a normal to decreased TIBC, normal to elevated serum ferritin and bone marrow storage iron, and a normal to decreased percentage saturation of transferrin. In addition to altered iron mobilization, a defective response of the bone marrow to circulating erythropoietin and a decrease in RBC life span during many chronic diseases are apparent. The anemia of chronic disease rarely is associated with clinical signs of decreased tissue oxygenation. Therapy is directed at the primary disease process. Oral iron supplementation is not indicated because systemic iron stores are usually normal to increased.

12.1.3.2.2.4

Bone Marrow Suppression.

Anemia caused by selective bone marrow suppression of erythropoiesis is unusual in the horse. Selective erythroid hypoplasia has been reported as a sequela to administration of recombinant human erythropoietin to horses.[130,131] Anemia is thought to result from production of antibodies that cross-react with erythropoietin, inhibiting erythropoiesis. Treatment is with blood transfusions and corticosteroids. Prognosis for recovery is fair to guarded.

Pancytopenia (decreased circulating erythrocytes, leukocytes, and platelets) has been described in horses with aplastic bone marrow disorders[132–134] and with myelophthisic diseases. Myelophthisis is a reduction in the cellular elements of the bone marrow, frequently a result of metastatic neoplasia or myelofibrosis, a proliferation of fibrous tissue in the marrow. Myelodysplasia implies accumulation of abnormal cells in the bone marrow. These cells are not usually dysplastic in the truest sense of the word, but rather they result from myeloproliferative neoplasia. Hematopoietic neoplasia is rare in the horse and is discussed in more detail later in this chapter. These conditions usually result in concurrent anemia, leukopenia, and thrombocytopenia. Diagnosis is by identification of abnormal cells in bone marrow aspirates.

Bone marrow from horses with aplastic anemia is generally devoid of hematopoietic precursor cells because of a congenital or acquired failure of stem cell function. Acquired aplasia may be associated with bacterial and viral infections, chronic renal or hepatic disease, neoplasia, irradiation, or drug therapy. In most cases, a predisposing factor is not identified.[132–137] Because of the shorter life spans of the cells,

leukopenia and thrombocytopenia usually precede anemia.[11] Diagnosis depends on bone marrow biopsy. If one cannot obtain adequate marrow by serial aspirates, one must obtain a core biopsy sample. Hypoplastic marrow is yellow because of fatty infiltration with a mixture of cell types, but the number of erythroid, myeloid, and megakaryocytoid cells is decreased.[11] Aplastic anemia is suspected to be an autoimmune disorder in some cases, and some horses have apparently benefited from therapy with corticosteroids and anabolic steroids.[132] These drugs stimulate erythropoietin production and increase sensitivity of the stem cell receptors to erythropoietin.

Temporary or permanent bone marrow aplasia has been associated with the administration of a variety of drugs in other species. Transient hypoplastic anemia following phenylbutazone administration has been reported in one horse.[138] Aplastic anemia has been induced experimentally by feeding of trichlorethylene extracted soybean oil meal to horses or by irradiation.[139] Chloramphenicol produces transient and irreversible forms of bone marrow dysfunction in human beings, and similar reactions are possible in other species. One always should handle chloramphenicol with caution because human toxic reactions appear to be idiosyncractic and may be associated with absorption of low amounts of the drug. One should discontinue any ongoing drug therapy in horses with aplastic anemia and should administer supportive therapy. Most cases of drug-induced bone marrow failure are temporary, and hematopoietic function returns to normal with time if secondary complications are not severe. One may adiminster compatible whole blood transfusions to horses with severe anemia or thrombocytopenia, and one may consider systemic antibiotics and strict isolation from other animals for horses with severe leukopenia.

Bone marrow erythropoiesis frequently is suppressed in horses with chronic renal disease. Suppression generally is attributed to a decrease in erythropoietin production by the kidneys. Recombinant 737
erythropoietin has been used successfully in cats and human beings with severe anemia associated with 738
renal disease.

12.2 Leukon

The leukon consists of circulating leukocytes, their precursor cells, and the tissues that produce them. This includes the granulocytes (neutrophils, eosinophils, and basophils), monocytes/macrophages, and lymphocytes. The leukon provides the primary effector cells for immune surveillance and clearance. This discussion provides a brief description of the production of these cells and their quantitative abnormalities in peripheral blood. Excellent pictures of the various developmental stages of equine leukocytes in the bone marrow and peripheral blood are available in other texts, and the reader is referred to these for identification of cell types.[11,12]

12.2.1 NEUTROPHILS

12.2.1.1 Physiology

Granulocytes and mononuclear phagocytes originate from a common committed progenitor cell in the bone marrow. Under the influence of cytokines—including granulocyte-macrophage colony-stimulating factor, monocyte colony-stimulating factor, granulocyte colony-stimulating factor, and various interleukins—this stem cell proceeds along a path to granulocyte or monocyte production. Cytokine signals for constitutive leukocyte production differ from those during periods of increased demand for specific cell types. The progenitor cell undergoes successive mitotic divisions from myeloblast (the first recognizable precursor of neutrophils) to promyelocyte and myelocyte. Mitosis does not occur as the cell matures from metamyelocyte

to band cell to mature neutrophil. Mature neutrophils are stored in the bone marrow until needed. The peripheral neutrophil pool is equally divided between circulating cells and cells adhered to the endothelium of small vessels (the marginated pool).[140] Circulating neutrophils have a half-life of 10½ hours in the horse[141] and eventually migrate into peripheral tissues, where they live several more days.

Neutrophils alter their distribution between storage, circulating, and marginating pools in response to various endogenous and exogenous stimuli. The marginating neutrophils are mobilized into the circulating pool in response to exercise, epinephrine, or stress. Glucocorticoids increase the rate of neutrophil egress from the bone marrow storage pool and decrease egress from the circulation.[142,143]

Neutrophils are attracted to sites of infection and inflammation by soluble chemotactic factors released during proinflammatory reactions. Neutrophils ingest and kill invading microorganisms and release additional factors that further propagate inflammation at the site of tissue injury.

The morphology of neutrophils on a stained smear of blood or body fluids (e.g., peritoneal or pleural fluid) aids in interpretation of the significance and severity of many disorders. Toxic changes in circulating neutrophils occur in response to inflammation and include cytoplasmic basophilia, cytoplasmic granulation and vacuolation, and appearance of Döhle's bodies (slate gray inclusions caused by retention and aggregation of rough endoplasmic reticulum).[12] Degenerative changes result from altered cell membrane permeability and include hydropic degeneration of the nucleus and a spreading out of the nuclear chromatin so that it more completely fills up the cytoplasm of the cell. Aged neutrophils may exhibit hypersegmented, pyknotic nuclei with round, tightly clumped chromatin. Aged neutrophils most commonly are visible in tissue fluids. Idiopathic hypersegmentation of blood neutrophils of one Quarter Horse, unrelated to any clinical disease, has been described.[144]

12.2.1.2 Disorders of Neutrophils

12.2.1.2.1 Neutropenia

Neutropenia is a decrease in the number of circulating neutrophils and may be acute, occurring transiently over 24 to 48 hours, or chronic, lasting several days to months. Acute neutropenia most commonly results from a shift of neutrophils from circulating to marginating pools. Endotoxin is a potent stimulus for margination of circulating neutrophils with sequestration in pulmonary capillaries.[140] Experimentally, administration of endotoxin to horses results in neutropenia within 90 minutes and return to baseline numbers within 6 to 18 hours.[145] Endotoxemia is probably the common denominator in the neutropenia associated with various equine gastrointestinal disturbances including strangulating obstruction, peritonitis, enteritis, and salmonellosis. Neutropenia is a common finding in acute septicemia in the adult and is considered an aid for diagnosis of sepsis in the neonate.[146] A variety of bacterial, rickettsial, and viral disorders also may be associated with neutropenia in the horse.

Chronic neutropenia may result from increased peripheral use of neutrophils or decreased bone marrow production. Neutropenia may accompany severe infectious or inflammatory diseases such as pleuritis, pneumonia, peritonitis, internal abscessation, enteritis, burns, vasculitis, or immune-mediated diseases. Neutropenia caused by increased use often is accompanied by appearance of immature cells in circulation. As tissue demand increases, the bone marrow releases progressively more immature band cells into circulation.[11] This regenerative left shift is an appropriate response to high tissue demand for neutrophils. In 738

animals with a degenerative left shift, the number of immature band cells or metamyelocytes in circulation exceeds the number of mature neutrophils because tissue use exceeds the capacity of the bone marrow to increase production.[12] A degenerative left shift is considered a poor prognostic indicator.

Neutropenia caused by bone marrow suppression may occur in horses with pancytopenia from a variety of causes (discussed previously). Myeloproliferative disorders including granulocytic leukemia also may result in chronic neutropenia.[147] Immune-mediated neutropenia has been described in human beings and in foals.[148,149] A syndrome of neutropenia and thrombocytopenia is described in related Standardbreds. A heritable cyclic neutropenia was suspected. Most affected horses died from complications of infectious diseases and/or thrombocytopenia.[150]

Administration of canine or bovine recombinant granulocyte colony-stimulating factor to normal newborn foals results in a profound increase in blood neutrophil count.[151,152] Anecdotally, administration of the factor has induced the same response in foals with neutropenia following septicemia or alloimmune disease. Recombinant granulocyte colony-stimulating factor is reported to improve recovery of adult horses when administered after experimental bowel resection.[153]

12.2.1.2.2 Neutrophilia

Many of the same disorders associated with neutropenia may be associated alternatively with neutrophilia. Endogenous or exogenous glucocorticoids or epinephrine, excitement, exercise, or stress may result in neutrophilia.[12,154] Any infection or inflammation in any part of the body may result in neutrophilia. Many neoplastic conditions also are accompanied by peripheral neutrophilia. A rebound neutrophilia is common in later stages of endotoxemia.

The magnitude of a neutrophilic response is determined by the balance between bone marrow production and tissue use. A regenerative left shift is not uncommon in animals with neutrophilia because of excessive tissue demand. A severe neutrophilia with significant left shift including metamyelocytes and myelocytes indicates serious inflammatory disease and is termed a *leukemoid response* because of its similarity to granulocytic leukemia.[11]

12.2.2 EOSINOPHILS

Eosinophils arise from the same bone marrow precursor as neutrophils and mononuclear phagocytes. They may be distinguished first from neutrophils at the early myelocyte stage and eventually develop characteristic bright red staining cytoplasmic granules. IL-5 is critical in the differentiation and maturation of eosinophils. The prominent cytoplasmic granules of eosinophils contain a variety of substances, including major basic protein, peroxidase, and various hydrolytic enzymes. Eosinophils are important in parasite immunity and are involved in some hypersensitivity reactions. Eosinopenia may result from acute infections, corticosteroid or epinephrine administration or release, or stress. Peripheral eosinophilia most commonly results from parasitic infections, including habronemiasis, stronglylosis, and pediculosis. Occasionally, allergic reactions also may result in peripheral eosinophilia. Eosinophilic myeloproliferative disease has been described in the horse.[155] A marked eosinophilia also has been seen in horses with lymphosarcoma and transitional cell carcinoma.[156]

12.2.3 BASOPHILS

Basophils also originate from the common granulocyte/macrophage precursor cell and mature into cells with basophilic cytoplasmic granules. They are the least common of the circulating granulocytes, and basopenia is not clinically significant. Basophils live in the blood approximately 6 hours and then migrate into tissues, where they exist another 10 to 12 days.[12] Basophils are involved in mediating some hypersensitivity reactions. Increased numbers of circulating basophils may occur with allergic, inflammatory, or neoplastic diseases or in association with lipemia.

12.2.4 MONONUCLEAR PHAGOCYTES

Monoblasts are the first recognizable bone marrow precursors of peripheral blood monocytes, originating from a pluripotent marrow precursor. After progressing through the promonocyte stage, monocytes are released into the peripheral blood where they circulate for a few days before migrating into tissues to mature into tissue macrophages. The role of mononuclear phagocytes in orchestrating immune and inflammatory reactions has long been underplayed. These cells are critical in regulating inflammation through release of proinflammatory cytokines such as tumor necrosis factor, IL-l, and platelet-activating factor. Mononuclear phagocytes phagocytose microbial organisms, particulate debris, and possibly neoplastic cells. They process these foreign antigens and present them to T lymphocytes in a form that initiates specific immune responses. They produce cytokines, including granulocyte-macrophage colony-stimulating factor, that are critical for regulation of hematopoiesis. They are responsible for removal of senescent cells and activated coagulation factors from circulation. Quantitative abnormalities of monocytes rarely are encountered in equine medicine, but monocytosis may be observed in some cases of chronic inflammation.

12.2.5 LYMPHOCYTES

Lymphocytes are the primary mediators of humoral and cell-mediated immune responses. They originate from an uncommitted bone marrow progenitor cell that is capable of differentiating into a committed lymphopoietic precursor or a granulocyte/macrophage precursor cell. Committed lymphopoietic progenitor cells differentiate 739
740 into T lymphocytes that mature during migration through the thymus or B cells that appear to differentiate in the marrow and then migrate to lymph nodes. Circulating lymphocytes are predominantly T cells and represent only a small fraction of the total lymphocyte pool. Most lymphocytes reside in the spleen, lymph nodes, and other lymphoid tissue of the body.

The spleen contains the greatest number of lymphocytes in the adult horse. The spleen plays a major role in immune defense. The large number of phagocytic cells in the spleen facilitates filtering of senescent blood cells, particulate debris, and microorganisms from the blood. Hemoglobin is degraded and iron is stored in splenic phagocytes pending reuse for erythropoiesis. The spleen is also important as a reservoir of RBCs and platelets, as discussed previously.

Lymphopenia is associated with glucocorticoid administration, stress, many viral infections, and combined immunodeficiency of Arabian foals. Lymphocytosis is associated with epinephrine administration, excitement, exercise, lymphocytic leukemia, and chronic immune stimulation. As horses age, the number of lymphocytes in their peripheral blood gradually decreases.[10,157]

12.2.6 HEMATOPOIETIC NEOPLASIA

12.2.6.1 Myeloid Neoplasia

Myeloid neoplasia is characterized by the unregulated proliferation of a bone marrow–derived blood cell line. The eventual outcome is severe myelophthisis with loss of normal marrow elements. Forms of myeloid neoplasia described in horses include granulocytic leukemia,[147] myelomonocytic leukemia,[158–161] monocytic leukemia,[162] and eosinophilic myeloproliferative disorder.[155]

No age predilection is apparent for equine myeloid neoplasia, for affected horses have ranged from 10 months[155] to 9 years of age.[147] Predominant clinical signs include depression, weight loss, edema, anemia, and mucosal petechial hemorrhages. Fever,[155,158,160,161] peripheral lymphadenopathy,[158,161] hemorrhagic diathesis,[155] and oral ulcers[158,159] were identified in some of the horses. Severe destruction of normal marrow architecture by the neoplastic cell line results in myelophthisic disease characterized by inadequate production of erythrocytes, platelets, and normal leukocytes. Most horses are anemic and have thrombocytopenia. The total white blood cell count of affected horses may be elevated, normal, or reduced, but abnormal leukocytes invariably occur in the peripheral blood. Abnormal leukocytes dominate in bone marrow aspirates.

The cause of myeloid neoplasia remains undefined. Clinical signs are caused by the loss of normal blood cells, which predisposes horses to hemorrhagic diathesis, infections, and inadequate oxygenation of tissues. The diagnosis in all reported cases was based on abnormal morphology of the circulating neoplastic leukocytes; the type of cell was delineated by cytochemistry or special stains. Treatment with cytotoxic agents in one case of acute myelomonocytic leukemia was unsuccessful.[161] All horses died or were destroyed humanely because of the effects of myelophthisic disease. Postmortem examination revealed abnormal leukocytes in various organs in addition to the bone marrow, most commonly in the lymph nodes, spleen, and liver.

12.2.6.2 Lymphoid Neoplasia

The most common type of neoplasia to involve the equine hemolymphatic system is lymphosarcoma.[163] Four anatomic forms have been described (generalized, intestinal, mediastinal, and cutaneous) based on the major site of tumor involvement[163,164]; however, the forms overlap substantially clinically and pathologically. The typical age of onset is between 5 and 10 years,[165] although lymphosarcoma has been documented in horses ranging in age from birth through 25 years.[166–168] No sex predilection exists. The incidence of lymphosarcoma is unknown, but the reported prevalence of affected horses at postmortem examination is 2% to 5%.[169,170]

12.2.6.2.1 Cause and Pathogenesis

A viral cause of equine lymphosarcoma has not been documented[171,172]; however, one report describes viruslike particles in the lymph node of a foal with lymphosarcoma that died shortly after birth.[168] Clinical signs and laboratory changes of lymphosarcoma generally are caused by loss of normal organ and tissue function following infiltration by lymphocytes or physical obstruction by tumor masses or the excessive generation of tumor cell products. Early reports suggested that some neoplastic lymphocytes were of the T

lymphocyte lineage.[173,174] However, more recent reports suggest that equine malignant lymphomata are composed of a heterogeneous cell population. Immunohistochemical analysis of biopsy specimens from 31 horses with lymphosarcoma revealed that 13 horses had diffuse lymphomata derived primarily from B lymphocytes, 11 additional horses had diffuse large B cell lymphomata containing 40% to 80% nonneoplastic T lymphocytes (T cell–rich, large B cell lymphoma), and 6 tumors were derived from neoplastic T lymphocytes. One diffuse large cell lymphoma did not react with B or T cell markers.[175]

Decreased serum concentrations of IgM and other indications of immunosuppression have been noted in horses with lymphosarcoma.[174,176–178] Other neoplastic lymphocytes may arise from autoreactive B cell clones that produce antibodies responsible for gammopathies and immune-mediated cytopenias. Neoplastic proliferation of large granular lymphocytes with natural killer cell activity was described in one horse.[179] 740

741

12.2.6.2.2 Clinical Signs and Laboratory Findings

The most common clinical signs of lymphosarcoma are chronic weight loss, ventral subcutaneous edema, and regional lymphadenopathy.[180,181] Peripheral lymphadenopathy is not observed frequently. Other clinical manifestations are highly variable depending on the organs involved and the duration of the disease process. Most clinical signs are progressive over weeks or months, although they may have a sudden onset.

Lymphosarcoma involving the thoracic cavity may cause tachypnea, dyspnea, cough, and pleural effusion.[166,182,183] If pleural effusion is present, one frequently identifies neoplastic lymphocytes by routine cytologic evaluation of fluid obtained by thoracocentesis.[183]

Extensive intestinal infiltration by neoplastic lymphocytes typically produces intestinal malabsorption, which contributes to hypoalbuminemia and weight loss. Affected horses frequently have abnormal glucose or xylose absorption indicative of extensive small intestinal malabsorption. In addition to weight loss, signs of gastrointestinal involvement may include colic or diarrhea.[184–186]

One may palpate splenic enlargement, internal lymphadenopathy, or abdominal masses on rectal examination. One may define the character of these masses further by ultrasonography.[187] Abdominocentesis may reveal inflammatory changes in the fluid (increased nucleated cell count and protein concentration), but identifying neoplastic cells in abdominal fluid of horses with alimentary or abdominal lymphosarcoma is not common.

The regional or generalized occurrence of multiple subcutaneous nodules with histopathologic characteristics of lymphosarcoma, unassociated with other lesions of lymphosarcoma, has been reported in horses.[163,188] Nodules may appear suddenly, grow slowly, remain static or regress, and recur at a later time. Hormonal factors including estrous cycle, pregnancy, lactation, and foaling may influence this cutaneous form of lymphosarcoma. In one horse, cutaneous lymphosarcoma cells were positive for progesterone receptors, and lesions regressed completely after surgical removal of an ovarian tumor.[189]

Tumor masses in localized areas may result in clinical signs referable to dysfunction of involved and adjacent tissues and organs.[171,180,182,190–195] Pharyngeal and laryngeal masses may result in dysphagia and unresponsive nasal discharge. Ocular lymphosarcoma may manifest as uveitis or as infiltrates in palpebral conjunctiva, eyelids, third eyelid, at the corneoscleral junction, or in the retrobulbar area.[196] Lymphosarcoma of the central nervous system may result in ataxia and cranial nerve deficits.[171,195,197]

The laboratory findings in horses with lymphosarcoma are highly variable. Hematologic indications of chronic inflammatory disease are common, including neutrophilic leukocytosis, nonresponsive anemia, hyperfibrinogenemia, and hypergammaglobulinemia.[181,182] Lymphocytic leukemia with peripheral lymphocytosis and large numbers of circulating neoplastic lymphocytes is rare and usually is associated with bone marrow involvement.[173,186,198–200] Although the lymphocyte count is usually normal or reduced, the presence of atypical or obviously neoplastic lymphocytes on a peripheral blood smear occurs in 30% to 50% of cases.[*] The total plasma protein concentration may be low, normal, or elevated, but the albumin:globulin ratio often is reduced, particularly with gastrointestinal involvement.[186,203] Polyclonal gammopathy is not unusual, and monoclonal gammopathy associated with serum hyperviscosity and a hemorrhagic diathesis has been described.[204] A mild elevation in liver-derived serum enzymes may occur following hepatic involvement. Hyperbilirubinemia usually is caused by anorexia or hemolysis.

A variety of paraneoplastic syndromes have been identified in association with equine lymphosarcoma. Hypercalcemia occasionally is reported.[192,205–207] Pseudohyperparathyroidism, resulting in hypercalcemic nephropathy and polyuria or polydypsia, has been reported in a horse with splenic lymphosarcoma.[208] In some patients, Coombs'-positive IMHA, immune mediated thrombocytopenia, or both may occur.[13,69,209] Hypereosinophilia has been reported in one pony with intestinal lymphosarcoma.[156] Concurrent intestinal lymphosarcoma and eosinophilic epitheliotrophic disease have been reported in a Paso Fino mare.[210] These two cases suggest the possibility that clonal proliferation of lymphocytes occasionally may result in hypersecretion of IL-5 with subsequent eosinophil activation. Paraneoplastic pruritus and alopecia also has been described in a horse with lymphosarcoma.[205]

* References 13, 173, 174, 181, 201, 202.

12.2.6.2.3

Diagnosis

The diagnosis of lymphosarcoma is by demonstration of neoplastic lymphocytes in affected tissue. Histologic examination of a biopsy from a tumor mass or affected lymph node is the most reliable method, and excisional biopsies are much preferred over needle biopsies or aspirates. Without lymph nodes or other masses accessible for biopsy, antemortem diagnosis is often difficult.[13,166,194,211] Diagnosis is only rarely possible on a peripheral blood smear[173,199] and generally requires careful cytologic evaluation of bone marrow, pleural effusion, or peritoneal fluid.[182,212,213] One rarely may find neoplastic lymphocytes by transcutaneous liver biopsy[202] and may use laparoscopy to see a mass better for biopsy.[166] Radiography and ultrasonography may be useful in locating and perhaps enabling biopsies of masses in the thorax or 741
abdomen. Often, diagnosis of lymphosarcoma is possible only by exploratory laparotomy or postmortem 742
examination.[13,184,194,211]

The morphology of neoplastic lymphocytes in horses is highly variable.[167] On cytologic preparations they often appear as large lymphoid cells with a variable nucleus-to-cytoplasm ratio, multiple nucleoli, nuclear chromatic clumping, cytoplasmic basophilia, and vacuolation. Mitotic figures and binucleate cells may be visible. The cytologic diagnosis of lymphosarcoma is best left to those experienced in evaluation of equine fluid specimens, because normal reactive lymphocytes and mesothelial cells may be difficult to distinguish from well-differentiated neoplastic cells. Histologically, the neoplastic cellular morphology also varies, but destruction of normal tissue architecture by a population of lymphoid cells aids the diagnosis.

12.2.6.2.4 Treatment

Experience in treating horses with lymphosarcoma is limited. Horses generally are debilitated greatly by the time of a diagnosis. Transient improvement in generalized forms has occurred following use of cytotoxic drugs, immunomodulators, and corticosteroids[180,211]; however, the long-term response is poor. Rarely, resection of localized tumors may be curative or significantly prolong survival.[214] The cutaneous form of lymphosarcoma may be responsive to corticosteroid and progestin therapy.[215] However, abrupt discontinuation or insufficient duration of therapy may result in recurrence of cutaneous lesions in a more aggressive and rapidly progressive form.

The prognosis for equine lymphosarcoma is grave. Most horses die or are destroyed humanely within 6 months of the onset of signs. Survival for a number of years rarely occurs. Survival times are longer for horses with cutaneous lymphosarcoma than for horses with internal organ involvement.

12.2.6.3 Plasma Cell Myeloma

Plasma cell myeloma (multiple myeloma), characterized by proliferation of neoplastic plasma cells in the bone marrow, spleen, liver, and lymph nodes, is rare in horses. Clinical signs include weight loss, weakness, recurrent fever, ventral edema, hemorrhage, lameness, and posterior paralysis.[216–220] Renal failure and infections are not uncommon. In human beings and dogs, skeletal pain and pathologic fractures result from neoplastic invasion of bone that causes osteolytic “punched-out” lesions[221,222]; osteolysis, however, does not occur consistently in horses.

Laboratory findings include anemia, hypercalcemia, azotemia, and hyperproteinemia with monoclonal gammopathy. Light-chain proteinuria (Bence Jones proteins) is variable. Criteria for diagnosis of plasma cell myeloma include plasmacytosis in the bone marrow or a soft tissue lesion, evidence of invasiveness, and the presence of monoclonal gammopathy or light-chain proteinuria.[221] Because of the overlap in histologic and clinicopathologic findings with some cases of lymphosarcoma, definitive diagnosis of plasma cell myeloma can be difficult.[204,223] Successful treatment of plasma cell myeloma in horses has not been reported.

12.3 Platelets

Platelets are circulating anucleate fragments of bone marrow megakaryocytes that are essential for the formation of primary hemostatic plugs. Platelets adhere to injured vascular endothelium, release substances that initiate and propagate hemostatic events, and provide a phospholipid surface for activation of several coagulation factors.[224] Platelets also are important proinflammatory elements that interact with endothelium, mononuclear phagocytes, neutrophils, and fibroblasts in initiation and propagation of inflammation.

12.3.1 PHYSIOLOGY

Platelets ultimately originate from the same pluripotent stem cell as erythrocytes and leukocytes. This stem cell undergoes successive divisions, becoming progressively more differentiated. The colony-forming unit megakaryocytoid cell is committed fully to platelet production. Polyploid megakaryoblasts double their DNA content by a process of endomitosis, resulting in megakaryocytes, the largest of the hematopoietic cells of the

bone marrow, within 5 days. The highly compartmentalized cytoplasm of the megakaryocyte ultimately disintegrates to release up to 8000 platelets into the peripheral circulation. Various cytokines, including IL-3, thrombopoietin, and IL-6, are essential for this process of differentiation, maturation, and release.

The mature platelet is a complex anucleate cell fragment that accumulates many substances in a variety of secretory granules. These include dense bodies containing adenosine diphosphate (ADP), adenosine triphosphate, calcium, and serotonin; α-granules that accumulate various procoagulant factors, albumin, platelet-derived growth factor, thrombospondin, and platelet factor 4; and lysosomal granules with acid hydrolases.[224] Glycoprotein receptor molecules are embedded in the external lipid bilayer membrane and interact with extracellular proteins that mediate platelet adhesion and aggregation. The external lipid membrane of the platelet invaginates into the interior to form a complex canalicular system important for secretory function. A second internal membrane system, the dense tubular system, supplies enzymes for arachidonic acid metabolism and is involved in sequestration and release of calcium.[225]

When a circulating platelet contacts exposed vascular subendothelial collagen, platelet surface receptors 742
recognize and attach to the damaged endothelium in a process known as adhesion. Normal adhesion requires von 743
Willebrand's factor (vWF), a glycoprotein found in vascular endothelium and platelets and present in plasma as a multimolecular complex with coagulation factor VIII. (The role of vWF in platelet adhesion is separate from the role of factor VIII in secondary hemostasis, which is discussed later. The two activities are referred to as VIII:vWF for the platelet adhesion mediated by vWF and as VIII:C for the coagulative protein.) Adhesion of platelets attracts additional platelets in a process known as aggregation. Primary aggregation is reversible and not associated with platelet degranulation. Irreversible secondary aggregation begins with release of ADP from platelet granules and production of thromboxane A_2 (TXA_2) via metabolism of arachidonic acid in the platelet membrane. Substances that promote aggregation usually do so by decreasing the concentration of intracellular cyclic adenosine monophosphate by inhibiting adenylate cyclase or by stimulating phosphodiesterase.[224] Equine platelets exhibit reversible aggregation when exposed to serotonin and arachidonic acid and exhibit irreversible aggregation when exposed to ADP.[226] Platelet-platelet bridging requires fibrinogen attachment to a newly exposed binding site on activated platelets.[225] Thrombospondin, a glycoprotein released from platelet α-granules, is also integral in the platelet aggregation response. Platelet aggregation is responsible for formation of the initial hemostatic plug (primary hemostatsis) at any site of vascular injury.

Arachidonic acid release from the membranes of the platelet-dense tubular network and its subsequent metabolism are critical to platelet aggregation. Arachidonic acid is a polyunsaturated fatty acid normally attached to the second glycerol carbon atom of many membrane glycerophospholipids. Arachidonic acid may be released by the direct action of phospholipase A_2 or by the sequential actions of phospholipase C and diglyceride lipase. Free arachidonic acid is metabolized via a cyclooxygenase pathway to form prostaglandins and TXA_2 or via a lipoxygenase pathway to form various eicosanoids. TXA_2 is a potent platelet activator, stimulating platelet aggregation and vasoconstriction. Although platelets preferentially produce TXA_2 via the cyclooxygenase pathway, vascular endothelial cells produce prostacyclin (prostaglandin I_2), a potent inhibitor of platelet aggregation and a strong vasodilator. The balance between TXA_2 production by platelets and prostacyclin production by vascular endothelium appears to regulate platelet aggregation in vivo.[224,225]

As with erythrocytes, platelets can be sequestered in the spleen and splenic contraction can increase the number of circulating platelets by 30% to 50%. In horses, splenectomy results in substantial and persistent increases in platelet counts.[12] Normal equine platelets have a life span of 4 to 5 days.[227] As platelets age, tissue macrophages of the spleen, liver, and bone marrow remove them from circulation.[228]

12.3.2

DISORDERS OF PLATELETS

12.3.2.1

Thrombocytopenia

Thrombocytopenia is a decrease in the number of circulating platelets. Normal platelet counts in the horse are slightly less than in other species, with higher counts in horses younger than 3 years of age and in male horses.[229] Most laboratories define thrombocytopenia in the horse as a peripheral platelet count of less than 100,000 per microliter. Clinical signs of thrombocytopenia in the horse reflect abnormal primary hemostasis and include petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased bleeding after venipuncture, melena, or hyphema.[230–235] Clinical bleeding usually is associated with platelet counts of less than 30,000 per microliter. Decreased numbers of circulating platelets can result from decreased production of platelets in the bone marrow, increased destruction of platelets, sequestration of platelets, or increased use of platelets during processes of coagulation (Box 12-5).

Proper sample collection and platelet counting is essential before one can make a diagnosis of true thrombocytopenia in a horse.[228] One can obtain an accurate platelet count in most horses from a blood sample obtained with EDTA as the anticoagulant. However, the platelets of some horses consistently clump in EDTA, resulting in an innacurate count or pseudothrombocytopenia.[236] An experienced technician always should examine a stained blood smear visually to assess the presence of platelet clumps. Platelet clumping may occur as a result of in vivo or in vitro platelet activation.[228] When in doubt, reassessing the platelet count in a blood sample anticoagulated with sodium citrate instead of EDTA is advisable. Platelet clumping and pseudothrombocytopenia also have been described in equine blood samples collected using low-molecular-weight heparin as an anticoagulant.[237]

12.3.2.1.1

Decreased Platelet Production

Thrombocytopenia only infrequently results from decreased platelet production.[238] One diagnoses primary bone marrow disease by bone marrow analysis and must exercise caution in interpreting megakaryocyte numbers from equine bone marrow aspirates. Megakaryocytes may be absent or present in low numbers in aspirates, even though adequate numbers are present in the intact marrow, possibly because of trapping of these large cells within the subendothelial layer of marrow sinuses. Bone marrow core biopsies are preferred for adequate evaluation of megakaryocyte numbers in the horse. Flow cytometric enumeration of thiazole orange–positive platelets in peripheral blood may be useful as a noninvasive test to assess platelet production.[239] 743

744

12.3.2.1.1.1

BOX 12-5 DIFFERENTIAL DIAGNOSES FOR THROMBOCYTOPENIA IN THE HORSE

12.3.2.1.1.1.1

Decreased Platelet Production

Hereditary defects

Myelophthisis

Myeloproliferative disease

Idiopathic pancytopenia

Myelosuppressive drugs

- Phenylbutazone
- Chloramphenicol
- Estrogens
- Trichlorethylene extracted soybean meal

Irradiation

12.3.2.1.1.1.2

Increased Platelet Use

Intravascular coagulation

- Disseminated intravascular coagulation
- Localized
    - Hemolytic uremic syndrome
    - Hemangioma

Hemorrhage

Thrombosis

12.3.2.1.1.1.3

Platelet Sequestration

Splenomegaly

12.3.2.1.1.1.4

Increased Platelet Destruction

Infectious diseases

- Equine infectious anemia
- *Ehrlichia equi*

Immune-mediated diseases

- Autoimmune disease
  - Systemic lupus erythematosus
- Idiopathic disease
- Secondary disease
  - Neoplasia (lymphosarcoma)
  - Bacterial infection
  - Viral infection
  - Drugs
- Neonatal alloimmune disease

Drugs or toxins

Snake bites

12.3.2.1.1.1.5

Laboratory Error

Because of the short life span of platelets in the peripheral circulation, thrombocytopenia is a common abnormality in animals with generalized bone marrow suppression of any cause. Thrombocytopenia with dramatically decreased bone marrow megakaryocyte numbers has been reported in horses with a variety of myeloproliferative disorders.[147,155,158,218] Thrombocytopenia also is recognized in horses with idiopathic pancytopenia[132,136] and drug- or toxin-induced myelosuppression.

A syndrome of neutropenia and thrombocytopenia has been described in related Standardbreds. A heritable cyclic neutropenia was suspected. Most affected horses died from complications of infectious diseases and/or thrombocytopenia.[150]

12.3.2.1.2

Increased Platelet Destruction

A variety of pathophysiologic events may increase the rate at which platelets are removed from circulation. Most of these disorders are accompanied by a compensatory bone marrow megakaryocytosis best identified with core marrow biopsies. Immunoglobulin deposition on the surface of platelets is the most common cause of accelerated platelet destruction. Cells of the mononuclear phagocyte system, especially splenic

macrophages and hepatic Kupffer's cells, remove antibody-coated platelets from circulation. Nonimmune mechanisms of accelerated platelet destruction include drug- or toxin-induced platelet damage and snake bites. Thrombocytopenia of controversial cause has been described in human beings and horses receiving heparin therapy.[240,241]

12.3.2.1.2.1 Immune-Mediated Thrombocytopenia.

Most cases of idiopathic thrombocytopenia in the horse likely are the result of an immune-mediated increase in platelet destruction. The initiating factors of this condition often are not identified, but immune-mediated destruction of platelets may be associated with viral or bacterial infections, neoplastic conditions such as lymphosarcoma, and with other autoimmune disorders, including autoimmune hemolytic anemia, glomerulonephritis, and systemic vasculitis.[230] Circulating platelets from human beings with immune-mediated thrombocytopenia (IMTP) have increased quantities of surface-bound IgG, IgM, or complement.[242–244] The mechanics of antibody attachment to platelets are similar to those described for IMHA. True autoantibodies may be produced against normal platelet surface antigens or against novel platelet antigens that have developed in response to a primary disease process. Circulating immune complexes may attach to platelets nonspecifically via Fc or complement receptors. Antibodies also may be directed against foreign molecules, such as drugs, that have attached themselves to platelet membranes. Regardless of the source of the antibody, mononuclear phagocytes remove immunoglobulin-coated platelets from the circulation, principally in the spleen and liver.[245]

Horses with IMTP may have petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased bleeding after venipuncture, melena, or hyphema.[230–235] Clinical bleeding usually is associated with platelet counts of less than 30,000 per microliter. Patient history and a careful physical examination 744
are critical for identifying underlying disease. An AGID or Coggins test for equine infectious anemia 745
(EIA) is indicated. One should evaluate other coagulation parameters, including prothrombin time (PT) and partial thromboplastin time (PTT), to identify complex coagulative defects such as those seen with disseminated intravascular coagulation (discussed in a subsequent section). A bone marrow analysis usually reveals normal to increased numbers of megakaryocytes. However, if antibodies against platelet membranes cross-react with megakaryocyte membrane antigens, megakaryocytes may be decreased or absent in the bone marrow.[246]

One can confirm a diagnosis of IMTP only with the demonstration of increased quantities of platelet-bound antibody, which may be measured indirectly with the platelet factor 3 test. Platelet factor 3 is a platelet membrane phospholipid released when platelets are injured. Addition of patient plasma containing released platelet factor 3 to platelet-rich plasma from a normal horse results in accelerated clotting of the sample. Unfortunately, this test is difficult to perform consistently, results vary, and most veterinary laboratories do not offer the assay. Direct fluorescent antibody testing and flow cytometric assay for platelet surface IgG and IgM have been described in horses with IMTP following EIAV infection.[99] Direct and indirect immunoradiometric assays and an indirect enzyme-linked immunosorbent assay for detection of platelet-bound antibody also have been described.[247,248] These tests are not widely available, however, and require careful control and interpretation. In the absence of an easy, accurate, and reliable method for definitive diagnosis of IMTP in the horse, one may make a presumptive diagnosis in horses with a low platelet count, normal coagulation parameters (PT and PTT), and no evidence of excessive consumption of platelets (disseminated intravascular coagulation).

One immediately should discontinue any current medication being administered to horses suspected of having IMTP. If life-threatening hemorrhage is occurring, transfusions of fresh whole blood or platelet-rich plasma are indicated. Most horses respond to therapy with parenterally administered corticosteroids.[230,234] Corticosteroids appear to act by suppressing the phagocytic activity of mononuclear phagocytes, inhibiting antibody synthesis, increasing effective platelet production, and reducing capillary fragility. One should tailor the corticosteroid dose and route of administration to the individual patient to achieve the best results with the lowest possible dose. Horses with IMTP have been reported to respond to dexamethasone at 0.1 mg/kg intravenously or intramuscularly twice daily.[231,234] One always should taper corticosteroid administration gradually to once-daily morning administration to decrease interference with endogenous corticosteroid release. If long-term maintenance therapy is necessary, every-other-day administration of the lowest effective dose is indicated. Maintenance therapy may be oral or parenteral. Potential complications associated with corticosteroid administration in the horse include laminitis, secondary infections, and iatrogenic hyperadrenocorticism.

Occasionally, horses with IMTP fail to respond to parenteral corticosteroid therapy. Two such horses responded favorably to azathioprine at 3.0 mg/kg orally once daily.[235] Azathioprine has been used in human beings and dogs with IMTP and acts as an immunosuppressive agent interfering with humoral and cell-mediated immune function. Vincristine is a vinca alkaloid used to treat refractory IMTP in human beings. Vincristine therapy was successful in treating one horse with idiopathic IMTP[249] and unsuccessful in treating another.[235] Alternative treatments for IMTP that have been effective in other species include danazol (a synthetic analog of androgenic steroids and progesterone), gammaglobulin infusions, and splenectomy.[250]

Neonatal alloimmune thrombocytopenia has been described in horse and mule foals.[247,248,251] A syndrome of presumptive neonatal alloimmune thrombocytopenia, mucosal erosions, and skin lesions has been described in foals of several breeds. These foals respond to supportive care with judicious administration of corticosteroids and transfusions of platelet-rich plasma. Long-term prognosis is good, but platelet counts can take 30 days or longer to stabilize above 10,000 per microliter.

12.3.2.1.2.2

Equine Infectious Anemia Virus.

Acute febrile episodes of EIAV are accompanied by a sharp decline in platelet count followed by a rapid rebound as fever and viremia resolve. This thrombocytopenia is probably multifactorial in origin. Circulating platelets have increased quantities of IgG and IgM on the surface[99] and show evidence of in vivo activation, possibly indicating enhanced non–immune-mediated destruction of platelets.[100] Bone marrow megakaryocytes are not infected during acute disease[99]; however, evidence exists of decreased bone marrow production of platelets in horses with EIA, possibly because of altered cytokine production in the bone marrow.[101,252,253] The thrombocytopenia of EIAV may contribute to petechia and ecchymoses but rarely is associated with a severe bleeding diathesis. EIAV is discussed in detail in previous sections.

12.3.2.1.2.3

Equine Granulocytic Ehrlichiosis.

Infection with the rickettsia *Anaplasma phagocytophilum* (formerly *Ehrlichia equi*) results in a syndrome of fever, anorexia, depression, petechia and ecchymoses, icterus, ventral edema, and ataxia lasting 3 to 16

days. Consistent hematologic abnormalities include thrombocytopenia, leukopenia, and mild anemia.[254,255] Clinical signs are more severe in adult horses than in those younger than 4 years of age. Foals younger than 1 year of age often experience only fever.[255,256] Granular inclusion bodies may be visible 745
in the cytoplasm of neutrophils and eosinophils during routine cytologic examination using any Wright's 746
or Giemsa type of stain. One may see inclusion bodies best under oil immersion, and they appear as pleomorphic, blue-gray to dark blue spoke-wheel shapes.[255] Inclusion bodies represent a cluster of coccobacillary organisms, varying in size from 0.2 to 5 μm in diameter, within cytoplasmic membrane-bound vacuoles. The appearance of cytoplasmic inclusion bodies correlates closely with the onset of fever, and they remain visible for approximately 10 days.[254]

Mortality is rare in horses with ehrlichiosis; most untreated animals recover over 2 weeks and acquire a sound immunity against reinfection for at least 2 years.[254,255] Treatment with oxytetracycline at 7 mg/kg intravenously once or twice daily for up to 7 days may hasten recovery. One should provide supportive therapy, including intravenous fluids, leg wraps, and stall confinement for the severely ataxic horse, as indicated.[254,255,257] In animals that die or are killed, necropsy lesions include petechial and ecchymotic hemorrhages, edema, and icterus. Histologically, small arteries and veins are inflamed, and mild inflammatory vascular or interstitial lesions may be present in kidneys, heart, brain, and lungs.[254] Most infected horses originate from the foothills of northern California, but infections also have been diagnosed in horses from other parts of the country.[256,257] Most cases of ehrlichiosis occur in late fall, winter, and spring. The disease is thought to be transmitted by ticks, but an exact vector has not been identified. Tick control is recommended for prevention of disease in endemic areas. Asymptomatic or mild infections occur in sheep, goats, dogs, cats, monkeys, and baboons.[258]

12.3.2.1.3 Increased Platelet Use

Rapid use of circulating platelets occasionally occurs and may be appropriate, as in the case of massive trauma or external hemorrhage, or inappropriate, as in some cases of systemic or localized activation of hemostatic mechanisms. Thrombocytopenia accompanying hemorrhage or trauma is usually mild to moderate and rapidly reversible. Disseminated intravascular coagulation (DIC) is a complex disorder of hemostasis resulting from widespread systemic activation of coagulation mechanisms. This microvascular coagulation rapidly uses circulating platelets, and thrombocytopenia is a common result. Affected animals have a variety of other abnormalities detectable by routine coagulation testing. Horses with DIC and normal platelet counts may have abnormal platelet function, inhibiting the use of those platelets. In one study of horses presented to a veterinary referral hospital, DIC following gastrointestinal or inflammatory diseases was the most common cause of thrombocytopenia.[238] The section on DIC provides more information on the pathophysiology, diagnosis, and treatment of the disease.

Localized activation of coagulation may occur in some disease conditions, including vascular tumors and renal disease. Thrombocytopenia has been reported accompanying hemangiosarcoma in the horse[259,260] and is associated with vascular tumors in human beings and dogs.[261,262] Hemolytic uremic syndrome is an unusual condition in the horse characterized by acute renal failure with microangiopathic intravascular hemolysis and disseminated or renal intravascular coagulation. Thrombocytopenia is a common finding in affected horses.[59,60]

12.3.3 THROMBOCYTOSIS

Thrombocytosis is an increase in the number of circulating platelets. Increased bone marrow production of megakaryocytes may occur as a primary myeloproliferative disorder or in association with other neoplastic conditions, including polycythemia vera. Thrombocytosis more commonly is associated with acute or chronic inflammatory disorders or follows acute hemorrhage.[263] Mild thrombocytosis also may occur during and immediately after exercise or excitement caused by splenic contraction and release of sequestered platelets into the peripheral circulation. Thrombocytosis is usually asymptomatic, and specific therapy is not indicated. Thrombocytosis rarely may be associated with venous thrombotic tendencies, and one may consider anticoagulative therapy.

12.3.4 FUNCTIONAL DEFECTS OF PLATELETS

Functional defects of platelets can result in clinical signs similar to those of thrombocytopenic patients, despite a normal to increased platelet count. The most widely used laboratory tests to assess platelet function are bleeding time and platelet aggregation studies. Bleeding time depends on the number and function of platelets, the level of vWF, and vascular integrity. One performs the test by inverting the lower lip and making a vertical incision 1 mm deep by 5 mm long, with a template bleeding time device (Surgicutt, International Technidyne Corp., Edison, New Jersey). After 30 seconds, one removes blood with Whatman filter paper; repeats the previous step every 15 seconds until one no longer detects blood on the filter paper; and records the total time.[264] Alternatively, one may make incisions on the caudolateral aspects of the forelegs with proximal venostasis using a sphygmomanometer cuff above the carpus.[265,266] One should shave the site before testing. Normal bleeding time varies, depending on the technique and site of incision, and one must establish the time for each technique. The veterinarian should evaluate a normal control horse concurrently with the patient. One may use a platelet aggregometer to measure the aggregation of platelets in response to ADP, serotonin, epinephrine, arachidonic acid, and collagen.[267,268] One should collect whole blood samples with sodium citrate as an anticoagulant and prepare platelet-rich plasma by centrifugation. 746

747

To the author's knowledge, congenital defects in platelet function have not been reported in the horse, but they are recognized in other species and should be considered in young animals. Von Willebrand's disease has been described in the horse.[269] Because the disease is not an inherent platelet defect, it is discussed later in this chapter, with hereditary defects of coagulation. Abnormal responses to platelet aggregating agents and increased bleeding time have been described in normal human and equine neonates,[264,268] and neonatal foals may have an increased susceptibility to platelet-associated hemorrhagic diathesis. Acquired platelet functional defects may be associated with uremia, acute myelodysplastic diseases, and dysproteinemias and following administration of various drugs.

Many human beings and animals with uremia exhibit abnormal hemostasis, most of which is attributable to abnormal platelet function and likely is caused by abnormalities in the biochemical processes necessary for platelet aggregation and granule release. Human beings with myeloproliferative and lymphoproliferative disorders have been reported to have abnormal platelet shapes and decreased aggregation and secretion.[270] Dysproteinemia in these patients may result in platelet dysfunction when abnormal proteins coat platelets or endothelium and interfere with normal adhesion and aggregation. A hemorrhagic diathesis caused by platelet dysfunction has been described in one horse with monoclonal gammopathy and lymphoproliferative disease.[204]

Drugs commonly used in equine medicine and associated with abnormalities of platelet function in human beings include penicillins, cephalosporins, quinidine, chlorpromazine, halothane, and NSAIDs.[270] NSAIDs act by inhibiting cyclooxygenase, an enzyme critical for the formation of prostaglandins, prostacyclins, and thromboxane from arachidonic acid. As previously discussed, TXA_2 is a strong stimulus for platelet aggregation and release reactions and is a potent vasoconstrictor. Aspirin covalently acetylates cyclooxygenase, and because platelets are anucleate cells, they are incapable of producing new enzyme. The result is an irreversible inhibition of platelet cyclooxygenase that can be corrected only when the body clears aspirin from the circulation and the bone marrow releases new platelets. In contrast, other NSAIDs produce only a temporary inhibition of cyclooxygenase by reversibly binding to the enzyme. Template bleeding time is prolonged in horses that have received aspirin, phenylbutazone, or flunixin meglumine.[266,267,271,272] The effect is most pronounced after aspirin therapy, and a dosage of 17 mg/kg once daily for 3 days increases bleeding time for at least 3 days after discontinuation of therapy.[266] The minimal effective dose of aspirin to decrease thromboxane generation is 5 mg/kg; the duration of decrease is dose dependent.[273]

12.4 Hemostasis

The vascular system provides a closed conduit for the circulation of fluid and cellular components of blood. Exchange of substances across the vessel surfaces is controlled carefully. The body must repair any disruption in the closed network of blood vessels rapidly and efficiently to prevent excessive loss of critical blood elements into the extravascular environment. This repair process requires interaction between the injured vessel wall, platelets, and soluble proteins and accessory molecules in the blood. The end result is a stable fibrin mesh that prevents loss of blood while the vascular endothelium regenerates. When endothelium has been repaired, fibrinolytic reactions occur to remove fibrin and reestablish vessel patency. A careful balance of coagulative and fibrinolytic processes must occur to maintain optimal circulatory capacity without loss of blood. The body also must control procoagulative forces carefully to prevent inappropriate activation that might result in thrombosis of normal vessels with subsequent tissue and organ ischemia.

12.4.1 PHYSIOLOGY

Primary hemostasis is the process of platelet interaction with the vessel wall to achieve a temporary plug of the vascular defect. Secondary hemostasis involves the interaction of soluble coagulation factors to produce a stable fibrin mesh that reinforces the platelet plug. The body carefully regulates hemostatic mechanisms via an intricate network of positive and negative feedback with inhibitors and potentiators of coagulation and fibrinolysis.

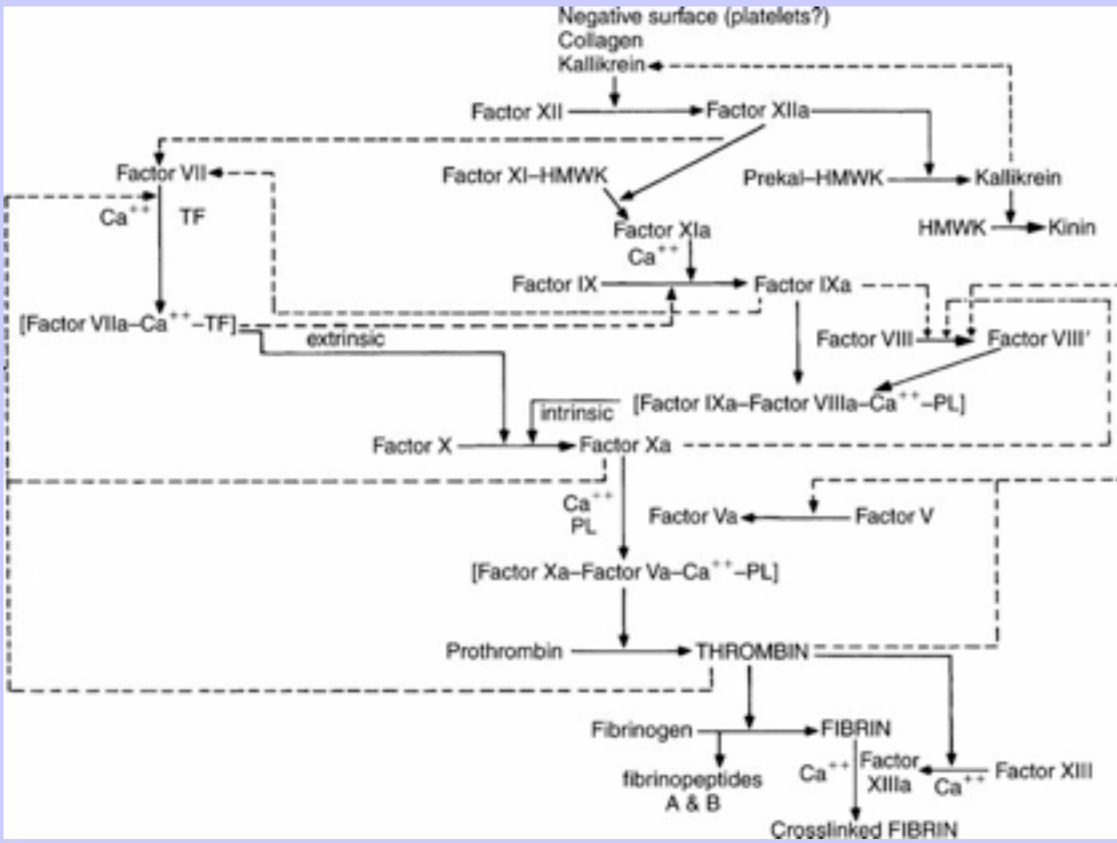
The initial vascular response to injury is intense vasoconstriction to divert blood from the site. Anticoagulative processes associated with vascular endothelium, including synthesis of prostacyclin and plasminogen activators and uptake and degradation of proaggregating molecules,[12] prevent the interaction of normal intact vascular endothelium with circulating platelets. Exposure of subendothelial collagen at the site of vascular injury triggers platelet adherence with interaction between endothelial vWF and platelet receptors. The function of platelets in primary hemostasis has been discussed in detail already. Platelet adhesion stimulates a release reaction involving platelet secretory granules. Contents of these granules (including ADP, adenosine triphosphate, serotonin, platelet factors 3 and 4, TXA_2, and acid hydrolases) attract other platelets in a process of irreversible platelet aggregation at the site of vascular injury. Platelet aggregation provides a favorable environment for accumulation and activation of the intrinsic and extrinsic coagulation systems.

The soluble coagulation factors (Table 12-3) participate in a cascade system that involves sequential activation of inactive precursor factors by limited proteolysis (Figure 12-2). Activated factors are indicated by the letter *a* following their numerical designation. Most coagulation factors are classified as serine proteases because of a critical serine residue at the active site of the enzyme. This serine is exposed following cleavage of a short peptide during activation of factor precursors. Although commonly discussed as separate pathways, intrinsic and extrinsic coagulation cascades interact at many levels and are considered more accurately as part of one highly complex system. For the sake of simplicity, however, they are discussed separately. The liver produces most soluble coagulation factors. Mononuclear phagocytes are responsible for clearing activated clotting factors from the circulation.

TABLE 12-3 Coagulation Factors

FACTOR	SYNONYM
I	Fibrinogen
II	Prothrombin
III	Tissue factor, tissue thromboplastin
IV	Calcium
V	Proaccelerin, labile factor
VI	Not assigned
VII	Proconvertin, stable factor
VIII	Antihemophilic factor
IX	Christmas factor
X	Stuart-Prower factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin-stabilizing factor
Prekallikrein	Fletcher factor
High-molecular-weight kininogen	Fitzgerald factor

Figure 12-2 Schematic representation of blood coagulation showing the numerous interactions between coagulation factors in the classic extrinsic and intrinsic pathways. *Arrow,* Primary action; *dashed arrow,* actions of secondary importance; *a,* activated form; *HMWK,* high-molecular-weight kininogen; *TF,* tissue factor; *PL,* phospholipids; *Prekal,* prekallikrein. (From Morris DD: Recognition and management of disseminated intravascular coagulation in horses, *Vet Clin North Am Equine Pract* 4:115-143, 1988.)



Contact of soluble coagulation factors with negatively charged subendothelial collagen and with the various products of the platelet release reaction initiates the intrinsic coagulation system. This initial contact phase (see Table 12-3) requires interaction of coagulation factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein to accelerate production of the activated form of factor XII (designated XIIa). Factor XIIa in turn catalyzes the limited proteolysis of factor XI to XIa. Elements of the contact phase reaction are also capable of inducing parallel proinflammatory reactions by initiating kinin and complement cascades. The importance of this contact phase reaction to in vivo coagulation is questionable. Human beings and animals with hereditary deficiencies of the proteins involved in this reaction (factor XII, HMWK, or prekallikrein) rarely show any 748 749

clinical bleeding tendencies. In contrast, deficiency of almost any other coagulation factor, including factor XI, results in profound hemorrhagic tendencies.

Factor XIa, in the presence of calcium, activates factor IX. Factor IXa forms a molecular complex with factor VIIIa and calcium on a phospholipid membrane surface to catalyze the conversion of factor X to Xa. Platelet membranes are thought to provide the phospholipid surface for this reaction. Activation of factor X is the point of interaction between the extrinsic and intrinsic systems.

The extrinsic coagulation system begins with formation of a molecular complex between tissue factor (thromboplastin), factor VIIa, and calcium ions on a platelet phospholipid surface to catalyze the conversion of factor X to Xa. Factor Xa is capable of activating factor VII to VIIa in a feedback loop that increases the production of both. In a slower reaction that appears to be important in vivo, the tissue factor VIIa–calcium complex is also capable of activating factor IX.[274] Tissue factor is present in virtually every tissue of the body, and a variety of insults can initiate the extrinsic coagulation system, including vascular endothelial damage, endotoxin, antigen-antibody complexes, RBC hemolysis, and local areas of tissue necrosis.

Formation of factor Xa marks the beginning of what classically is termed the *common pathway of coagulation*. Factor Xa complexes with factor Va and calcium on a phospholipid membrane to convert prothrombin to thrombin enzymatically. Thrombin in turn is the catalyst for formation of fibrin from fibrinogen. Thrombin is also important in the activation of factors V, VIII:C, and XIII, forming positive feedback loops that potentiate the coagulative process and promote platelet aggregation. Fibrin monomers aggregate, and factor XIIIa catalyzes the formation of covalent cross-linkages between the monomers to stabilize the clot.

Inhibitors of procoagulative elements in part maintain a balance between clot formation at sites of vascular injury and pathologic thrombosis. Two physiologically important systems for in vivo procoagulant inhibition have been described. The most important of these is plasma antithrombin III (AT III), responsible for 50% to 75% of plasma antithrombin activity. AT III inhibits all serine proteases generated during the coagulation process, including thrombin; factors Xa, IXa, XIa, and XIIa; plasmin; kallikrein; and the anticoagulants protein C and protein S. Heparin interacts with AT III, causing a conformational change that increases the activity of AT III 1000-fold.[275] The second main anticoagulative system involves protein C and protein S, two vitamin K–dependent serine proteases that inhibit coagulation at the level of factors Va and VIIIa. Protein S is a cofactor for protein C, required for binding of activated protein C to platelet and endothelial cell surfaces.

The fibrinolytic system is responsible for eventual remodeling and removal of a stable fibrin clot to restore blood flow (Figure 12-3). Because small amounts of fibrin production and subsequent fibrinolysis occur continuously in vivo, the body must maintain a delicate balance between procoagulant and fibrinolytic processes to prevent widespread thrombosis or hemorrhage. The principal enzyme of the fibrinolytic system is plasmin, normally present in plasma as an inactive precursor, plasminogen. Plasminogen is converted to plasmin proteolytically by endothelial tissue plasminogen activator, an enzyme present in most normal and neoplastic tissue. Endothelial cells adjacent to clot formations release tissue plasminogen activator in response to vascular stasis and a high local concentration of thrombin. Released tissue plasminogen activator has a high affinity for fibrin, localizing it to the adjacent clot for plasminogen activation. Circulating antiplasmins, the most important of which is α_2-antiplasmin, rapidly inactivate circulating plasmin. Plasmin bound to fibrin is much less accessible for inactivation because plasmin interactions with fibrin obscure binding sites for inhibitors.[276]

Plasminogen also may be activated during the contact phase of the intrinsic coagulation system. Factor XIIa and HMWK interact with prekallikrein to produce kallikrein. Kallikrein activates urokinase, which in turn converts

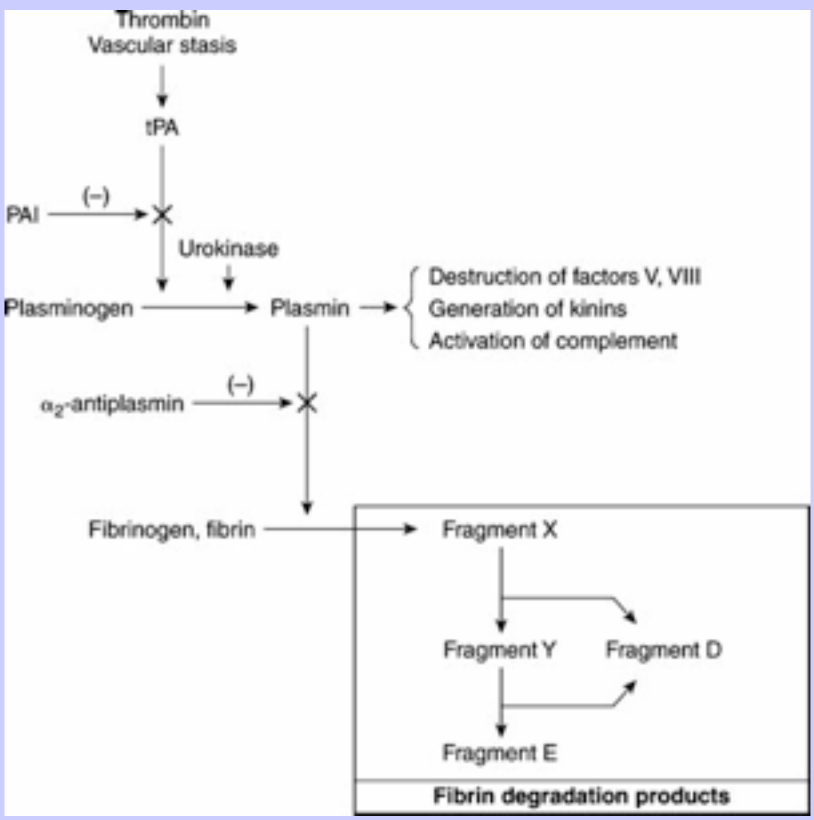
plasminogen to plasmin.[277] Because plasmin can activate factor XII, a potential feedback loop amplification exists. The importance of contact phase activation in vivo is questionable, however.

Plasmin is a serine protease with a high affinity for fibrinogen and fibrin, degrading them into fibrin degradation products (FDPs). Plasmin also may aid in degradation of factors V, VIII, IX, and XI. Fibrin and fibrinogen are split into the clinically significant FDPs, fragments X, Y, O, and E. The mononuclear phagocytes of the liver clear FDPs from the circulation.

12.4.2 EVALUATION OF HEMOSTASIS

Disorders of hemostasis usually may be classified based on clinical signs as abnormalities of primary or 749
secondary hemostasis. Abnormalities of primary hemostasis include vascular diseases and changes in the number 750
or function of platelets. Affected horses usually have signs of mucosal bleeding, petechia and ecchymoses, epistaxis, hyphema, or melena. Platelet function tests were discussed previously. Diagnosis of the vasculitides is discussed in another section.

Figure 12-3 Major fibrinolytic reactions (see text for details). A negative sign (–) indicates inhibition of a specific reaction. *TPA,* Tissue plasminogen activator; *PAI,* plasminogen activator inhibitor. (From Kobluk CN, Ames TR, Geor RJ: *The horse: diseases and clinical management,* Philadelphia, 1995, WB Saunders.)



Disorders of secondary hemostasis usually involve abnormalities in quantity or function of the soluble coagulation factors and present as spontaneous or excessive hemorrhage in response to surgery or trauma. These horses may have hemorrhage into body cavities, hematoma formation, hemarthroses, prolonged bleeding after venipuncture, or external hemorrhage. Most coagulation tests measure the time necessary for clot formation under various circumstances. Coagulation times tend to be longer in horses than in human beings or other domestic animals.[278] Table 12-4 lists some laboratory tests used to assess equine hemostatic function with normal reference values.

Activated clotting time measures the time to clot formation on activation of whole blood by contact with 750
diatomaceous earth. This process bypasses the contact phase of the intrinsic cascade and is useful in evaluating 751
deficiencies of factors VIII and IX, prothrombin, and fibrinogen. Abnormalities of factor VII and platelets do not appear to alter the activated clotting time.[278] One collects blood directly into a tube containing diatomaceous earth, mixes, incubates the contents at 37° or 38° C, and measures the time until clot formation.

TABLE 12-4 Reference Ranges for Equine Hemostatic Values*

PARAMETER	UNITS	VALUE	REFERENCE
Platelet count	per µl	75,000–300,000	NCSU
Fibrinogen	g/dl	<400	NCSU
Prothrombin time	seconds	8.5–9.9	NCSU
APTT	seconds	30–44	NCSU
FDPs	mg/dl	<20	NCSU
AT III	% PNEP	63–131	279
AT III	% PNHP	218±18	280
Plasminogen	% PNEP	64.6–155.9	281
Protein C	% PNEP	104.5±13.8	282

NCSU, North Carolina State University College of Veterinary Medicine clinical pathology laboratory normal equine reference values; *APTT,* activated partial thromboplastin time; *FDPs,* fibrin degradation products; *AT III,* antithrombin III; *PNEP,* pooled normal equine plasma; *PNHP,* pooled normal human plasma.

* These numbers are for reference only. Each laboratory should establish its own normal equine values.

PTT and activated PTT (APTT) measure the function of the intrinsic and common coagulation pathways, including factors XII, XI, X, IX, VIII, and V, prothrombin, and fibrinogen. One performs the PTT test by adding platelet-poor plasma to a glass tube containing phospholipid emulsion and calcium and determining the time to clot formation. One performs the APTT test similarly, except one adds an activating agent. PT, also known as one-stage PT, measures the function of the extrinsic and common coagulation pathways, including factors V, VII, and X, prothrombin, and fibrinogen. One mixes platelet-poor plasma with thromboplastin and calcium and determines the time to clot formation. One may use citrated whole blood or plasma for accurate measurement of PT up to 3 days after collection. A control sample from a clinically normal horse should accompany the patient's sample.[283] Thrombin time measures the time to clot formation after addition of thrombin to citrated plasma. Thrombin time is only prolonged with abnormalities in fibrinogen quantity or function or in the presence of thrombin inhibitors.

One most commonly measures FDPs in the serum using antibody-coated latex beads and monitoring macroscopic agglutination. This test reflects only the presence of D and E fragments. One must collect blood into a special tube containing thrombin and a protease inhibitor (ThromboWellcotest, Burroughs Wellcome Co., Research Triangle Park, North Carolina). One usually determines fibrinogen concentration by heat precipitation and determines plasma protein concentration before and after heating to 57° to 68° C for 3 minutes and centrifugation to remove precipitated fibrinogen. The difference in plasma protein concentration after heating and centrifugation approximates the plasma fibrinogen concentration.

Tests for plasma AT III measure the presence or the activity of the protein. Because inactive AT III antigen may be present, functional tests are preferable. Assays of AT III activity are clotting or chromogenic tests that measure residual thrombin activity after one adds the patient sample to a known quantity of thrombin. Normal AT III activity in the horse has been reported as 218% of normal human pooled plasma[280] and 63% to 131% of normal equine pooled plasma.[279,284] Widespread in vivo activation of coagulation is the most common cause of decreased plasma AT III activity. Decreased activity also is associated with protein-losing enteropathies or nephropathies. Increased activity has been reported in horses with hepatic disease.[284] AT III may act as an acute phase reactant, increasing in animals with acute inflammatory reactions.

Specialized assays for various components of the equine procoagulative and fibrinolytic systems have been described but are not yet widely available. These include assays for protein C,[282] plasminogen,[281] α_2-antitrypsin,[285] vWF,[269] and factor VIII:C.[286]

12.4.3 HEREDITARY DISORDERS OF HEMOSTASIS

Inherited disorders of hemostasis are most common in purebred animals that have been highly inbred. Many of these disorders are inherited in an autosomal recessive fashion; both parents must be carriers of the disorder to produce clinically affected offspring. For practitioners to be able to differentiate between inherited and acquired disorders of hemostasis is essential to advise owners appropriately. Inherited disorders are potentially treatable, but they are incurable. Owners should not use affected animals and their carrier parents as breeding stock. Practitioners see most animals with inherited bleeding problems when they are still young. Owners frequently complain of inappropriate bleeding in response to trauma or surgery or apparently spontaneous external hemorrhage or hematoma formation. As with any inherited defect, one should obtain a careful history and examine the patient and any close relatives, including siblings and parents, if possible. Most inherited defects result from a single factor abnormality. Routine coagulation studies may narrow the differential diagnoses for these bleeding disorders, but confirmation of diagnosis usually requires specialized tests. In contrast, most acquired defects of hemostasis are characterized by multiple factor abnormalities, frequently with a severe underlying systemic disorder.

12.4.3.1 von Willebrand's Disease

vWF is a glycoprotein of plasma, platelets, and endothelium required for platelet adhesion to exposed subendothelium and subsequent normal platelet plug formation. In plasma, vWF is bound in a multimolecular complex to coagulation factor VIII. Quantitative or qualitative abnormalities of vWF result in spontaneous bleeding from mucosal surfaces and excessive bleeding after surgery or trauma. Von Willebrand's disease has been reported in one Quarter Horse filly[269] presented for episodes of oral bleeding, conjunctival hemorrhage, and prolonged bleeding at injection sites and in a Thoroughbred mare and foal presented for episodes of

epistaxis. Routine complete blood count, including platelet count and coagulation profile, was within normal limits. In the related Thoroughbreds with von Willebrand's disease the APTT was prolonged because of decreased factor VIII:C concentrations, whereas values for PT were within reference ranges.[287] Assays for vWF quantity and function were abnormal. This condition is heritable in human beings and dogs, and owners should not use affected animals for breeding. 751 752

12.4.3.2 Abnormalities of the Contact Phase of Coagulation

The initiation of the intrinsic coagulation system involves interaction of factor XII, prekallikrein, and HMWK ultimately to activate factor XI. This process usually begins with contact between factor XII and negatively charged molecules such as subendothelium or collagen. Prekallikrein deficiency has been diagnosed in families of Belgian horses[288] and American Miniature Horses.[289] Plasma prekallikrein deficiency is characterized by prolonged APTT with a normal PT. Affected horses may or may not show clinical signs of a bleeding tendency.[288,289] Confirmation of diagnosis is by demonstrating low prekallikrein activity with normal activity of other intrinsic coagulation factors. One also can correct the prolonged APTT by extended incubation with a contact activator.[288,289] In human beings, prekallikrein deficiency is inherited as an autosomal recessive or autosomal dominant trait.[290] The mode of inheritance in horses has not been confirmed, but appearance of the defect in multiple members of some equine families strongly suggests that it is an inherited disorder in this species as well. A similar defect in the contact phase of coagulation, not thought to result from prekallikrein deficiency, was diagnosed in one Quarter Horse gelding with prolonged APTT and normal PT.[291] Researchers did not observe a clinical bleeding problem in association with this defect.

12.4.3.3 Factor VIII Deficiency

Classic hemophilia (factor VIII deficiency, hemophilia A) is the most commonly reported inherited defect of hemostasis in the horse. Hemophilia has been diagnosed in Thoroughbred, Standardbred, Quarter Horse, and Arabian colts[286,292–299] with severe spontaneous hemorrhage or excessive hemorrhage related to surgery or mild trauma. Coagulation testing reveals abnormal function of the intrinsic coagulation system, with a prolonged APTT and a normal PT. Confirmation of diagnosis is by measuring factor VIII:C activity in plasma. In human beings the severity of clinical signs varies inversely with this value, and the same appears to be true for affected horses. In severely affected horses, factor VIII activity is less than 10% of normal equine plasma.[286,294,296] A less severely affected colt that survived castration and was undiagnosed until 3 years of age had a factor VIII activity of 20% to 30%.[298] As in human, canine, and feline hemophilia, equine factor VIII deficiency is transmitted as an X-linked recessive trait.[293] Carrier mares transmit the defect to 50% of their male offspring on average. Carrier female horses usually have a factor VIII:C activity of approximately 50% of normal, although this value may vary widely and even overlap normal values. No cure exists for hemophilia, and the disease is progressively debilitating and potentially lethal. Affected human beings are treated with repeated transfusions of fresh plasma and factor concentrates. Factor IX and XI deficiencies have been reported in one Arabian foal with concurrent factor VIII deficiency.[295]

12.4.4 ACQUIRED DISORDERS OF HEMOSTASIS

12.4.4.1 Vasculitis

Vasculitis, inflammation of blood vessels, may occur as a primary disease process but more commonly is encountered as a secondary complication of infectious, immunologic, toxic, or neoplastic disorders.[300] Hypersensitivity vasculitides are characterized by predominant involvement of small blood vessels in the skin. In most cases the postcapillary venules are involved. The most common inflammatory pattern is leukocytoclasis, defined by the presence of neutrophilic nuclear debris in and around the involved vessels. Vessel wall necrosis and fibrinoid changes occur.

Clinical signs depend on the type of vessel affected and the severity of the inflammatory response. Vascular occlusion may result in tissue ischemia and necrosis. Increased vascular permeability results in hemorrhage and edema as fluid and cellular constituents of the blood escape into the extravascular space. In horses, vasculitis is characterized by well-demarcated areas of cutaneous edema that may involve any portion of the body.[301] The distal extremities and ventral body wall are affected most commonly, and the edematous area is often hot and painful. Affected horses generally are depressed and reluctant to move. Hyperemia, petechial and ecchymotic hemorrhages, and ulcerations are commonly present on mucous membranes of the mouth, nose, vulva, etc. Other clinical signs may reflect edema, hemorrhage, and infarction in other body systems. Lameness, colic, diarrhea, dyspnea, or ataxia can result from involvement of vessels in joints, muscles, gastrointestinal tract, respiratory tract, and central nervous system. Subclinical renal disease may occur. Secondary complications such as laminitis, thrombophlebitis, and localized infections are common. Affected skin often weeps serum and eventually sloughs.

The underlying disease, length of illness, other organ involvement, and secondary complications usually determine hematologic and serum biochemical findings in vasculitis; none are characteristic. Neutrophilia, mild anemia, hyperglobulinemia, and hyperfibrinogenemia usually accompany chronic inflammation. The 752
platelet count is generally normal unless concomitant consumptive coagulopathy or IMTP exists. With renal 753
involvement, serum creatinine may be elevated or urinalysis may reveal hematuria or proteinuria or both.

12.4.4.2 Infectious Diseases

Infectious diseases associated with vasculitis and subsequent petechiation, ecchymoses, and dependent edema include EIAV, equine granulocytic ehrlichiosis, and equine viral arteritis (EVA). All three diseases may result in thrombocytopenia, although this is somewhat less common with EVA. The first two are discussed in detail elsewhere in this chapter; a discussion of EVA follows.

Equine viral arteritis is characterized by fever, chemosis, lacrimation, rhinitis, focal dermatitis, ventral edema, and occasionally abortion.[302,303] Many infected horses do not show recognizable clinical signs. Equine arteritis virus officially is classified in the *Arterivirus* genus of the Arteriviridae family.

Horses become infected by aerosol or venereal contact with an infected animal. The virus replicates in the intima and media of most arteries, resulting in an inflammatory reaction and cellular influx.[304] Stallions may become asymptomatic carriers of the disease, harboring virus in the accessory sex glands[302,305] and transmitting infection to previously unexposed mares. Infected mares make an uneventful recovery from EVA

and eliminate the virus from their body. Abortion may occur during or shortly after acute illness or asymptomatic infection as a result of myometrial necrosis and edema leading to placental separation and fetal death.[306] Not all infected mares abort, however, and the incidence of abortion may be strain dependent.[307]

One confirms diagnosis of EVA in mares by serologic assay, demonstrating a fourfold or greater rise in titer between acute and convalescent serum samples. EVA titer may remain elevated for a long time after natural infection, and recovered mares are considered immune to further infection. Diagnosis of persistently infected asymptomatic stallions depends on isolation of the virus from semen samples or demonstration of seroconversion of an otherwise unexposed mare within 2 weeks of breeding to the suspect stallion.[308] Diagnosis of abortion caused by EVA requires virus isolation from the fetus or the placenta. Recent seroconversion in the mare is highly supportive of a diagnosis of EVA abortion. One may offer supportive care to acutely infected animals and should isolate them from uninfected animals, especially pregnant mares. A modified live virus vaccine is available.[307]

12.4.4.3 Immunologic Diseases

Most noninfectious cases of vasculitis in the horse are thought to be immune-mediated. Small cutaneous vessels most commonly are affected, resulting in edema that may progress to skin infarctions, necrosis, and exudation.[300] The best characterized of these disorders is purpura hemorrhagica following *Streptococcus equi* subsp. *equi* infection. However, vasculitides of undetermined cause also have been described in the horse.[233,309] Most of these cases appear to have an immune-mediated cause. The antigenic stimulus of hypersensitivity vasculitis is usually a microbe, drug, toxin, or foreign or endogenous protein. The deposition of circulating immune complexes with subsequent vessel wall damage is probably the major event in the pathogenesis of these vasculitic syndromes. Soluble immune complexes, formed in moderate antigen excess, become deposited in blood vessel walls in areas of increased permeability. Deposited immune complexes activate complement with resulting formation of C5a, a potent chemotactic factor for neutrophils. Infiltrating neutrophils release lysosomal and other cytoplasmic enzymes such as elastase and collagenase that directly damage vessel walls. The net effect is vessel wall leakage and luminal compromise, resulting in edema, hemorrhage, thrombosis, and ischemic changes in supplied tissues.

Aside from vessel wall necrosis, vasculitis results in vascular dysfunction characterized by a net increase in vasoconstriction and platelet aggregation, which contribute to tissue ischemia.[310] The diseased endothelium releases endothelin, a polypeptide that causes contraction of underlying smooth muscle[311] and produces fewer dilator substances such as endothelial-derived relaxing factor.[312] Injury to the vessel wall also results in diminished prostacyclin production, which usually serves to maintain vasodilation and platelet nonreactivity.[313] Thus endothelial dysfunction contributes ultimately to vessel failure following vasculitis.

The factors that determine which individuals develop hypersensitivity vasculitis remain undefined. Genetic predisposition, altered immunoregulatory mechanisms, and the amount, relative size, and type of complement components in circulating immune complexes are important in determining the potential risk of developing vasculitis, because these factors determine how quickly the mononuclear phagocyte system clears immune complexes.[314] Perhaps even more significant in this potential risk are genetic and acquired differences in the number and activity of receptors for complement and IgG on erythrocytes and macrophages. The difference can affect immune complex handling and distribution greatly.[315,316] Receptors for complement and the Fc of IgG mediate immune complex transport to and removal by the macrophages of the mononuclear phagocyte system. Physical factors such as turbulence of blood flow, hydrostatic pressure within vessels, and previous

endothelial damage likely determine the size, type, and location of blood vessels involved in vasculitis. The propensity for lesion formation in skin of dependent body portions likely is caused by the hydrostatic pressure in affected postcapillary venules in these areas.[313] 753 754

12.4.4.4 Diagnosis

The diagnosis of vasculitis depends on demonstration of typical histologic changes (e.g., leukocytoclasis and fibrinoid necrosis) in involved vessels. One should obtain full-thickness punch biopsies (6 mm in diameter) of skin in an affected area and preserve it in 10% formalin for histopathologic study. One can process the samples saved in Michel's transport medium subsequently for immunofluorescence analysis to detect immune complexes.[317] Multiple biopsies from various sites are optimal in reaching a diagnosis, because distribution of histologic lesions and immune complexes is patchy; however, affected skin is often on the distal limbs where risk increases for cellulitis or exuberant granulation tissue. The irregular distribution of histologic lesions, coupled with difficulty in obtaining biopsies, makes the definitive diagnosis of vasculitis difficult. Often a diagnosis of vasculitis is based on history, clinical signs, and response to therapy.

Purpura hemorrhagica is a syndrome of cutaneous vasculitis that frequently develops several weeks after infection with *S. equi* subsp. *equi, S. equi* subsp. *zooepidemicus,* influenza virus, or equine herpesvirus. Purpura hemorrhagica also has been described as an adverse side effect of antistreptococcal vaccination in the horse. Purpura hemorrhagica after infection with *S. equi* subsp. *equi* has been attributed to deposition of circulating immune complexes consisting of IgA and *S. equi* subsp. *equi* M protein in small subcutaneous vessels.[318] Horses are often febrile with ventral edema, especially of the distal limbs. Affected animals frequently have great pain and are reluctant to move. Petechia and ecchymoses may be present on oral, nasal, and conjunctival mucous membranes. Extensive skin necrosis and sloughing often follow severe swelling. Horses with purpura hemorrhagica are not usually thrombocytopenic but frequently have laboratory evidence of chronic inflammatory disease, including increased fibrinogen and total plasma protein, and neutrophilia.[300] Cutaneous biopsy of affected areas may confirm the diagnosis. Histopathologically, a leukocytoclastic vasculitis characterized by neutrophilic accumulation in and around small dermal and subcutaneous vessels occurs.

12.4.4.5 Treatment

The aims in the therapy of equine vasculitic syndromes are (1) to remove the antigenic stimulus if possible, (2) to reduce vessel wall inflammation, (3) to normalize the immune response, and (4) to provide supportive care. Regardless of the cause, vasculitis in horses generally warrants aggressive nursing care, which one should institute immediately. Hydrotherapy can minimize edema, and pressure wraps are useful on the limbs. Animals that become severely depressed and fail to drink or those with dysphagia caused by pharyngeal edema require fluids, intravenously or via nasogastric tube. A tracheostomy may be necessary in horses with stridor and dyspnea following edema of the upper respiratory tract. Phenylbutazone, flunixin meglumine, or other NSAIDs are indicated to reduce vascular inflammation and provide analgesia. The disease also may warrant corticosteroid administration. Antimicrobial therapy may reduce the incidence or severity of cellulitis or other septic sequelae.

Because no treatment effectively eliminates the viruses of EIA or equine arteritis virus from the body, neither disease warrants specific therapy. Although equine ehrlichiosis spontaneously resolves, elimination of the organism by oxytetracycline therapy considerably shortens the clinical course of disease.

When the cause is unknown, vasculitis can be difficult to treat because the antigenic stimulus remains undefined and may not be eliminated easily. One should discontinue administration of any drug being used at the time that signs occur. A thorough search for an underlying infection or neoplasia is warranted. Horses with a recent history of strangles or that have been exposed to the disease should receive procaine penicillin G at 22,000 U/kg intramuscularly twice daily or potassium penicillin G intravenously 4 times daily for at least 2 weeks. One should drain accessible abscesses. Even though the sensitizing infection usually has resolved by the time signs of purpura hemorrhagica occur, ongoing sepsis and antigen production prolong the allergic vasculitis. The use of corticosteroids for treating hypersensitivity vasculitis remains controversial[313]; however, clinical experience suggests that horses with purpura hemorrhagica or idiopathic vasculitic syndromes respond favorably to corticosteroid therapy.[300]

Mild cases of vasculitis may resolve without immunosuppressive therapy, but life-threatening edema involving the upper respiratory tract or causing organ system dysfunction necessitates early aggressive corticosteroid treatment. One should administer dexamethasone (0.05 to 0.2 mg/kg intravenously or intramuscularly once or twice daily) at the dose and rate necessary to reduce edema. One may substitute prednisone 0.5 to 1.0 mg/kg orally twice daily for dexamethasone, but prednisone often is not as effective, possibly because of poor oral absorption of the drug. After edema and hemorrhages start to resolve, one may reduce the corticosteroid dose gradually (by 10% to 15% every 1 to 2 days) while carefully monitoring the horse for relapse. For horses with purpura hemorrhagica to require corticosteroid therapy for a period of 4 to 6 weeks before edema permanently resolves is not uncommon. 754

755

Occasionally, horses suffer disease flare-ups that require the corticosteroid dose to be increased over the previously efficacious level. In these instances, flunixin meglumine may enhance steroid efficacy. Antimicrobials are indicated throughout the period of systemic corticosteroid administration to reduce the incidence and severity of secondary sepsis.

12.4.4.6 Prognosis

The prognosis for vasculitis depends on the initiating disease process. With early aggressive therapy and supportive care, most horses recover from purpura hemorrhagica within 4 weeks, although numerous sequelae may prolong the convalescence. Dermal infarction in the distal limbs often leads to skin sloughing followed by exuberant granulation tissue and may require excision followed by skin grafting. Laminitis and various infections such as cellulitis, pneumonia, colitis, and thrombophlebitis are common and may be related to long-term corticosteroid therapy.

EVA and equine ehrlichiosis carry a good prognosis, and disease confers some immunity to reinfection. Horses with EIA are infected persistently and may suffer recurrent clinical relapses. Horses with idiopathic vasculitic syndromes have an unpredictable response to therapy, and some have a poor prognosis. Inadequate resolution of hypersensitivity vasculitis in human beings usually is caused by failure to identify the antigenic stimulus or completely eliminate it from the body.[313] Although in most horses remission is spontaneous, some have debilitating cutaneous disease or develop systemic necrotizing vasculitis with a poor prognosis.

12.4.5 THROMBOCYTOPENIA

When circulating platelet counts decrease to less than 30,000 per microliter, a bleeding diathesis frequently occurs. Affected horses have petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased

bleeding after venipuncture, melena, or hyphema.[230–235] Similar signs may occur in horses with platelet function defects. Disorders involving alterations in platelet number or function are described in foregoing sections.

12.4.6 VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin essential for a final step, γ-carboxylation, in the hepatic synthesis of many coagulation factors. The serine proteases, including factors II, VII, IX, and X, require γ-carboxylation of glutamate before they are biologically functional. Vitamin K deficiency results in a gradual decrease in functional coagulation factors in circulation that ultimately can end in a clinical syndrome of inappropriate bleeding. The rapidity with which coagulation factor concentrations in circulation decline depends largely on the half-life of those factors in circulation. Factor VII has a plasma half-life in the dog of 4 to 6 hours (compared with 41, 14, and 16 hours for factors II, IX, and X, respectively) and reaches a critical concentration in the circulation more rapidly than other vitamin K-dependent factors.[319] As a result, coagulation studies early in the course of vitamin K deficiency may reveal abnormalities in the extrinsic coagulation system (prolonged PT) with a normal intrinsic system (normal APTT). As the condition progresses, however, extrinsic and intrinsic coagulation parameters are abnormal.

All green leafy feeds, including hay and fresh pasture, contain high concentrations of vitamin K. Vitamin K also is thought to be synthesized by the intestinal microflora of many species. As a result, vitamin K deficiency only rarely results from an absolute deficiency of the nutrient in the diet. More commonly, deficiency results from an inability of the horse to absorb or use dietary vitamin K. Chronic intestinal malabsorption of lipids can result in clinical bleeding problems. One may assess dietary fat absorption by feeding 150,000 IU of vitamin A (another fat-soluble vitamin) in corn oil with grain and measuring increases in serum vitamin A concentration.[320] Concentrations should double over 12 to 24 hours. Fat absorption depends on bile acid secretion from the liver, and chronic cholestatic disorders also can result in decreased vitamin K absorption.

Antagonism of vitamin K by warfarin or other dicumarol derivatives is a more common clinical problem than is absolute vitamin K deficiency. The dicumarol derivative warfarin has been advocated as an oral anticoagulant for use in horses with navicular disease[321] or jugular thrombophlebitis.[322] Warfarin also is the active ingredient in many rodenticides, and accidental exposure to toxic doses of the compound is possible. Warfarin is an effective antagonist of vitamin K and inhibits the production of functional coagulation factors II, VII, IX, and X. Warfarin therapy may begin with a daily dose of 0.018 mg/kg orally and increase in increments of 20% to achieve the desired therapeutic effect,[321] which usually results in a final dose of 0.012 to 0.75 mg/kg daily.

Concurrent administration of other drugs, especially phenylbutazone, may increase the risk of warfarin-induced hemorrhage. Phenylbutazone acts by competing with warfarin for binding sites on plasma albumin, increasing the concentration of free warfarin in circulation. Similarly, hypoalbuminemia can increase the risk of warfarin toxicosis. Thyroxin and corticosteroids lower the necessary therapeutic dose of warfarin by enhancing receptor affinity and increasing clotting factor catabolism. Rapid withdrawal of drugs that induce hepatic microsomal enzyme metabolism, such as rifampin, chloramphenicol, and barbiturates, also can potentiate toxicosis because these drugs enhance warfarin metabolism. 755

756

Because factor VII has the shortest half-life of the vitamin K–dependent factors, warfarin affects the extrinsic coagulation system more rapidly than the intrinsic system, and determination of PT is the most commonly used method for monitoring the effectiveness of warfarin anticoagulative therapy. An increase in PT of 1.5 to 2.5 times baseline (15% to 25% of normal activity) is recommended as a therapeutic goal of warfarin anticoagulation.[322,323]

Toxic doses of warfarin result in spontaneous hemorrhage that may be life-threatening. One makes a diagnosis of warfarin toxicity based on a history of exposure, clinical evidence of hemorrhage (bleeding from body orifices or into body cavities, hematoma formation, or clinical pathologic indications of blood loss anemia), prolonged PT or PTT with normal platelet count and fibrinogen and FDP concentrations, and response to exogenous vitamin K administration.[324]

Because warfarin interferes with the final stages of clotting factor synthesis, administration of vitamin K_1 at up to 1.0 mg/kg subcutaneously rapidly reverses toxicity.[322] One may repeat this dose every 4 to 6 hours until PT returns to normal, followed by daily monitoring for 3 to 4 days.[325] PT returns to normal approximately 5 days after the last dose of warfarin without administration of supportive therapy; administration of vitamin K_1 results in a return of PT to baseline within 24 hours.[325,326] In horses with severe bleeding, one should administer whole blood transfusions concurrently to replace plasma clotting factors. The horse should improve within 1 to 2 hours. One may administer smaller doses of vitamin K_1 orally, concurrent with warfarin, to titrate the anticoagulant effects of the latter.[326]

Second-generation anticoagulant rodenticides such as brodifacoum have a prolonged half-life (1.2 days) and lower median lethal dose compared with warfarin.[327] As a result, their potential for adverse effects are greater. Accidental exposure to these agents necessitates more prolonged antidotal therapy.[328]

Toxicosis caused by ingestion of moldy sweet clover (*Melilotus* spp.) hay is reported in all herbivores.[329] White sweet clover *(Melilotus alba)* and yellow sweet clover *(Melilotus officinalis)* contain coumarin. When sweet clover hay is cured improperly, numerous fungi (*Penicillium, Mucor,* etc.) propagate; these fungi convert coumarin to 4-hydroxycoumarin, which condenses to dicumarol.[330] Animals that ingest sufficient quantities of moldy hay develop severe coagulation dysfunction within 2 to 7 days with internal and external hemorrhaging.[331] Continued ingestion of moldy hay can result in a lethal hemorrhagic crisis. One should suspect toxicity as a diagnosis in horses with history of access to moldy sweet clover hay and can confirm the diagnosis with coagulation tests described previously for warfarin toxicosis. Suspect hay should be destroyed because toxic concentrations of dicumarol may remain for up to 4 years.[330]

One may treat clinical bleeding episodes resulting from inadequate vitamin K and subsequent deficiency in the levels of vitamin K–dependent coagulation factors in circulation with parenteral vitamin K_1 (phylloquinone) injections and may administer a dose of 0.3 to 0.5 mg/kg. Subcutaneous injection is recommended because intravenous administration has resulted in a high incidence of adverse reactions in other species. One ultimately must address underlying gastrointestinal or hepatic disorders as well. Parenterally administered vitamin K_3 (menadione sodium bisulfite) is nephrotoxic in horses at the manufacturer's recommended dose and should not be administered.[332] Horses that receive vitamin K_3 may show signs of colic, hematuria, azotemia, and electrolyte abnormalities consistent with acute renal failure.

12.4.7 HEPATIC DISEASES

Severe hepatic disease often is associated with hemorrhagic tendencies caused by decreased production of coagulation factors II, V, VII, IX, and X and fibrinogen. Impairment of bile acid secretion may impair absorption of the fat-soluble vitamins, resulting in decreased production of the vitamin K–dependent clotting factors. Hepatic Kupffer's cells also are responsible for removal of many activated coagulation factors and FDPs from the

circulation. Increased circulating FDPs inhibit normal platelet function and generation of fibrin. These abnormalities may combine to initiate DIC. A severe bleeding diathesis is a poor prognostic indicator in horses with hepatic disease.

12.4.8 DRUG-INDUCED ALTERATIONS IN HEMOSTASIS

A variety of pharmaceutic agents can alter hemostatic mechanisms. Incorrect or poorly monitored administration of these agents may result in hemorrhagic tendencies in the horse.

12.4.8.1 Aspirin

Aspirin causes an irreversible inhibition of platelet function. The mechanisms and implications of this effect were discussed previously.

12.4.8.2 Heparin

Heparin is a mucopolysaccharide complex of variable molecular weight that potentiates the activity of AT III in neutralizing coagulation factor X and increasing the rate of inactivation of other serine proteases (factors II, IX, XI, and XII).[333,334] Potentiation of AT III activity is attributed primarily to lower molecular weight forms 756
of the molecule that inhibit factors X and XII, with minimal inhibitory effects on thrombin and factors IX and 757
XI.[334] Heparin has been advocated for maintenance of the patency of indwelling catheters, prophylaxis for venous thrombosis and laminitis, anticoagulation of whole blood transfusions, prevention of postoperative peritoneal adhesions, and treatment and prevention of DIC.[333,335–337] Heparin efficacy in most of these conditions has not been confirmed.[338,339] Bleeding complications associated with heparin therapy are uncommon, but administration of protamine sulfate at up to 1 mg for every 90 to 100 U of heparin has been recommended in horses with heparin-associated hemorrhage.[333] Protamine sulfate forms a stable salt with heparin and with soluble fibrinogen monomers. If the FDP concentration increases in a patient, precipitation of these salts may result in intravascular infarction, and use of protamine sulfate is contraindicated.

The most pronounced adverse effect associated with heparin administration in the horse is a significant reduction in the circulating RBC mass.[240,340] Doses of 160 to 320 U/kg subcutaneously twice daily for nine doses resulted in a significant decrease in RBC numbers, PCV, and total hemoglobin, and an increase in MCV, with a rapid return of values to baseline after discontinuation of therapy.[240] Because heparin is known to increase the activity of mononuclear phagocytes, decreased RBC numbers originally were hypothesized to result from an enhanced phagocytosis of erythrocytes.[340] However, decreased RBC numbers now are thought to result primarily from in vivo erythrocyte agglutination.[341,342] One can reverse this agglutination in vitro by adding a trypsin solution to the RBC suspension. Decreases in RBC numbers and increases in MCV associated with heparin administration are most likely artifactual, resulting from the measurement of multiple agglutinated cells as single units.[342] Heparin administration in horses (160 U/kg subcutaneously twice daily) also has been associated with development of large plaques of painful edema.[343]

12.4.9 DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a condition of pathologic activation of coagulative and fibrinolytic systems, ultimately leading to microvascular ischemia and secondary organ dysfunction. DIC may be acute or chronic, systemic or localized,

and frequently is characterized by severe hemorrhage caused by consumption of coagulation factors but also may be manifest as a pronounced thrombotic tendency. The type and severity of clinical signs depend on the initial stimulus for pathologic systemic coagulation activation, the duration and extent of activation, the availability of coagulation factors, and the relative strengths of activation of procoagulant and fibrinolytic forces. The final result in horses with severe DIC is often widespread ischemic organ failure, severe hemorrhage, and death.

DIC is not considered a primary diagnosis and occurs following a variety of disorders triggered by many different mechanisms. In the horse, DIC most commonly is associated with gastrointestinal disease or sepsis.[344–354] The common initiating factor in most cases is endotoxin, the external lipopolysaccharide cell wall of gram-negative bacteria. Endotoxin can activate factor XII directly to initiate the intrinsic coagulation pathway and may cause widespread damage to vascular endothelium, exposing subendothelial collagen and releasing tissue thromboplastin to trigger the intrinsic and extrinsic coagulation pathways. Endotoxin damages platelets, inducing a platelet release reaction and exposing platelet factor 3. Other conditions associated with DIC include intravascular hemolysis, bacteremia (gram positive or gram negative), viremia, neoplasia, circulating immune complexes, immune thrombocytopenia, fetal death in utero, burns, hepatic disease, renal disease, and vasculitides. Virtually any primary disease process may initiate DIC by injury to blood cells, increasing the availability of phospholipid surfaces, injury to vascular endothelium, or tissue injury and subsequent release of thromboplastin.[355]

In addition to coagulative abnormalities, widespread activation of proinflammatory pathways occurs, including generation of kinins and stimulation of the complement cascade.[355] Factor XIIa is responsible for initiating kinin formation by activating kallikrein, which in turn proteolytically converts HMWK to kinins. Bradykinin, the most physiologically important of the kinins, enhances vascular permeability, dilates some blood vessels, and stimulates migration of leukocytes into the extravascular space.[356] Plasmin activates the complement cascade and induces neutrophil chemotaxis, increases vascular permeability, and destroys RBCs and platelets, releasing membrane phospholipoprotein and ADP to act as procoagulants. Complement products can activate factor XII.

Tissue mononuclear phagocytes become activated during disseminated coagulation and inflammation. In response to endotoxin, these cells release procoagulant substances including tissue factor, platelet activating factor, tumor necrosis factor, and IL-l.[357] These phagocytic cells are responsible for removal of activated clotting factors and FDPs from the circulation. Massive concentrations of activated clotting factors or FDPs, or impairment of phagocytic function, can lead to abnormally high levels of either element in the blood. Activated clotting factors then remain available for continued coagulative events. Elevated FDP levels in the peripheral circulation can inhibit fibrin monomer polymerization and thrombin formation and also coat platelet membranes, interfering with aggregation.

757

758

The clinical signs associated with DIC in the horse vary widely and reflect the primary disease process, the duration and severity of coagulation activation, and the balance between procoagulant and fibrinolytic forces. Horses seldom show severe bleeding diathesis following DIC. Careful clinical examination may reveal petechia and ecchymoses of mucous membranes and prolonged bleeding from venipuncture sites. Many horses exhibit an increased tendency to venous thrombosis after venipuncture.[348] Other clinical signs may reflect organ dysfunction following microvascular thrombosis and tissue ischemia. In the kidney, organ dysfunction may occur as tubulointerstitial disease and acute renal failure. In the foot, DIC may contribute to digital ischemia and laminitis[335,336,344,348]; however, experimentally induced laminitis was not associated with significant changes in hemostatic parameters.[285] Many horses with DIC have clinical signs reflecting poor peripheral perfusion and shock, including prolonged capillary refill time, cool extremities, and tachycardia, which may result from the primary disease process or occur following DIC-induced microvascular occlusion and inflammation.

Diagnosis of DIC depends on the results of a variety of tests assessing the quantity and function of coagulative substances. The most commonly evaluated parameters in horses are platelet count and function, PT, PTT, activated clotting time, and FDPs. Platelet counts usually are decreased in horses with DIC.[345–348,350,353] In horses with normal platelet counts, platelet function frequently is impaired.[344] Although early in the disease coagulation times may be shorter, rarely does one examine horses at this time. Most horses have reached a stage of hemorrhagic tendency, largely because of consumption of coagulative elements, by the time DIC is recognizable. These patients have increased PT, PTT, and activated clotting time. Because DIC accelerates fibrinolytic processes, elevations in circulating FDPs occur commonly.[344,348,350,353] In contrast to other species, horses with DIC commonly have normal to increased fibrinogen concentrations.[344,348,353] Fibrinogen acts as an acute phase reactant protein in the horse, and inflammation, which accompanies most cases of DIC in the horse, stimulates accelerated hepatic production.

Several other laboratory tests that may aid in diagnosis of DIC in the horse are not yet as widely available. Plasma AT III concentrations are considered a sensitive indicator of DIC in human beings.[358] Because AT III is bound irreversibly to serine proteases in the plasma, AT III is consumed rapidly during pathologic intravascular coagulation. AT III activity has been shown to decline in horses with experimentally induced large colon torsion.[351] This decline was reversible in horses that survived and persisted in horses that died. In horses with naturally occurring colic or acute colitis, plasma AT III activity is decreased significantly.[279,345,346] One does not always find decreases in AT III activity, however, and normal activity has been reported in ponies with coagulopathy following equine ehrlichial colitis.[349] Because AT III is a small protein, it may be lost from circulation in most disease conditions associated with hypoalbuminemia, including protein-losing enteropathies and nephropathies.[359] Increased plasma AT III activity has been associated with hepatic disease in the horse.[279]

Assays for equine α_2-antiplasmin, plasminogen, and protein C have been described, and normal values have been reported.[281,282,285] Plasma α_2-antiplasmin concentrations were decreased in ponies with coagulopathy following equine ehrlichial colitis. Plasminogen concentrations were increased in these ponies, possibly indicating a role of plasminogen as an acute phase reactant.[349] Plasma protein C concentrations may be decreased in human beings with DIC.[360] One may determine individual coagulation factor levels, but such determination rarely provides more information than PT or PTT.

Diagnostic criteria for DIC in the horse have not been defined rigidly. One must assess each patient in the light of the severity and duration of underlying disease processes, clinical appearance, and laboratory hemostatic values. One may document subclinical DIC with laboratory evaluation of animals that have no overt clinical signs of pathologic coagulopathy. Multiple hemostatic abnormalities in an animal with thrombotic or hemorrhagic tendencies strongly suggest DIC.

The therapeutic plan for horses with DIC must focus on treatment of the primary underlying disease process. Only by removing the pathologic stimulus for coagulation can procoagulant and fibrinolytic mechanisms be rebalanced effectively. One should administer supportive therapy for shock, decreased tissue perfusion, and acid-base/electrolyte abnormalities. If endotoxemia contributes to the disease process, one should administer NSAIDs. Low-dose flunixin meglumine therapy (0.25 mg/kg intravenously 3 times daily) is effective in inhibiting endotoxin-induced cyclooxygenase activity.[361] One should treat animals with sepsis with appropriate antimicrobial agents. One may adminstered fresh platelet-rich plasma intravenously to horses with life-threatening hemorrhage following DIC. Fresh plasma resupplies soluble coagulation factors, and normal platelets may restore primary hemostatic mechanisms. Administration of whole blood or blood products remains

controversial in treatment of patients with DIC because of the potential for worsening the coagulopathy on administration of fresh coagulation factors. One must consider this possibility, but in the face of life-threatening hemorrhage, benefits may outweigh risks.

Heparin therapy has been advocated for DIC in other species. Because heparin acts as an anticoagulant by complexing with AT III to inhibit serine proteases, AT III levels must be normal to achieve any benefits from 758
heparin therapy. Heparin administration is controversial in the horse because of a tendency to cause erythrocyte 759
agglutination and anemia in vivo.[240,342] Heparin has been advocated to decrease the incidence and severity of laminitis after gastrointestinal surgery, but no benefit has been documented.[338] Similarly, no significant difference in survival was apparent with heparin therapy after exploratory celiotomy in the horse.[339]

Early recognition of DIC and aggressive therapy of underlying disease conditions remain the most effective treatments for the horse with pathologic coagulopathy. Understanding the pathogenesis and diagnosis of DIC will aid the practitioner in this process.

12.4.10 THROMBOSIS AND THROMBOPHLEBITIS

A thrombus is an intravascular accumulation of fibrin, platelets, and leukocytes that usually occurs at a site of endothelial damage. Three factors may predispose a horse to vascular thrombosis: vascular endothelial injury, vascular stasis or slowing of blood flow, and abnormalities of coagulation processes. After vascular damage, thrombus formation is the normal end result of procoagulative forces. However, pathologic or abnormal thrombus formation may occur in patients with an imbalance of procoagulative and fibrinolytic forces, as in DIC.

The horse appears to be particularly prone to superficial vein thrombosis during periods of systemic activation of coagulation. Jugular vein thrombosis may occur in these animals after a single, apparently atraumatic, venipuncture. Clinical impressions suggest that endotoxemic/septicemic horses have an increased susceptibility to thrombosis at the site of indwelling venous catheters. Bilateral jugular vein thrombosis leads to increased intravascular pressures proximal to the thrombus formation and severe edema of the head. This edema may impair respiratory function, necessitating tracheostomy. If one suspects that sepsis is contributing to thrombus formation, one should initiate appropriate antibiotic therapy. If one suspects hypercoagulation as a predisposing factor for thrombosis, aspirin administration at 20 mg/kg every other day may be beneficial to inhibit platelet aggregation and release reactions.[271,273] Hot compresses and hydrotherapy may improve collateral blood flow and decrease inflammation at the site of thrombosis. The thrombus eventually should recanalize and venous flow should return. One may assess recanalization and the size of the thrombus with ultrasound examination of blood flow through the affected vessel.[362] If an underlying disease process is present, one always should direct primary care at correcting this disorder. In horses with unilateral jugular vein thrombosis, one should protect patency of the opposite jugular vein by minimizing prothrombotic trauma to that vessel, including venipuncture or catheter placement.

12.5 Blood and Blood Component Therapy

Treatment of a variety of equine disorders involves administration of whole blood, plasma, or other blood constituents. One must base therapeutic decisions on clinical signs, laboratory parameters, availability of suitable donor services, and economic considerations.

12.5.1 WHOLE BLOOD TRANSFUSION

One most commonly administers blood transfusions to horses with anemia severe enough to impair tissue oxygenation. Tachycardia, tachypnea, lethargy, weakness, cool extremities, and pale mucous membranes indicate significant tissue hypoxia and may occur at a PCV as high as 18 or as low as 10, depending on the rapidity of erythrocyte loss. Chronic anemias allow for physiologic adaptation to the low circulating RBC numbers, and severe clinical signs may not be apparent until the PCV is extremely low. Fresh whole blood transfusions also may be indicated in horses with severe hemorrhage associated with DIC to renew supplies of soluble coagulation factors and platelets.

Donor animals should lack detectable circulating alloantibodies against erythrocyte antigens that might be present in the recipient.[363,364] One can use crossmatching to detect existing antibody before transfusion. One should collect EDTA-anticoagulated blood and serum from the recipient and from several potential donor horses. The major crossmatch checks for compatibility between donor RBCs and any alloantibody that might be present in patient serum. The minor crossmatch assesses compatibility between alloantibody that might be present in donor serum and patient RBCs.[12] Both tests are important before transfusion of whole blood; the minor crossmatch is most critical when one contemplates plasma transfusion.

Transfusion of RBCs may sensitize the recipient to produce alloantibody against any incompatible erythrocyte antigens present in donor blood. For this reason, one should consider routine use of donors that are negative for factors Aa and Qa to prevent the inadvertent sensitization of brood mares against the two most common alloantigens involved in neonatal isoerythrolysis, Aa and Qa.

If crossmatching is not possible, one may consider unmatched transfusion for critical patients. One must weigh the potential adverse effects of a transfusion reaction against the potential benefits to the patient. Most horses without previous transfusions may safely receive a single transfusion or multiple transfusions over 3 to 4 days from an unmatched donor. Chances of an adverse reaction increase when either donors or recipients are mares 759
that have been bred previously. For this reason, male horses or female horses that have never been pregnant are 760
preferred as donor animals for unmatched transfusions.

One safely may remove 5 to 10 L of blood from most adult donor horses. All equipment used for blood or blood product collection and administration should be sterile, and one should perform all procedures with strict attention to aseptic technique. Stock solutions of acid citrate dextrose anticoagulant are available commercially. Alternatively, one may use sodium citrate as an anticoagulant, mixing one part of a 3.2% sodium citrate solution to nine parts whole blood. Plastic blood collection bags with premeasured anticoagulant are convenient and effective for use with horses. Little information is available about the effects of storage on equine whole blood, and use of donor blood immediately after collection is preferable.

The volume of blood administered to a patient depends on the severity of RBC depletion and the total blood volume. A recommended formula for calculating this is as follows[365]:

$$\text{body mass (kg)} \times \text{blood volume (ml/kg)} \times \frac{(\text{PCV desired} - \text{PCV observed})}{\text{PCV of donor blood}}$$

Normal blood volume in adult horses is approximately 72 ml/kg.[366] In neonates, blood volume is 151 ml/kg, decreasing to 93 ml/kg at 4 weeks, 82 ml/kg at 12 weeks, and adult values by 4 to 6 months of age.[367]

Transfused RBCs survive less than 1 week in the horse, sometimes less than 2 days, and multiple transfusions may be necessary to maintain a patient until bone marrow production can exceed the rate of peripheral RBC destruction or loss.[368]

One should administer blood products through an intravenous system with an in-line filter. Even with crossmatching of donor and recipient, one should administer the initial 25 to 50 ml of transfused blood slowly over 15 to 30 minutes with close monitoring of patient heart rate, respiratory rate, and behavior. If these parameters remain stable, one may administer the remainder of the transfusion at a rate of 15 to 25 ml/kg/hr. One should give transfusions to horses with suspected or confirmed endotoxemia or septicemia more cautiously.

Several adverse reactions, immediate or delayed, may be associated with administration of blood or blood components and may be characterized by increases in heart and respiratory rates, dyspnea, fever, trembling, weakness, hypotension, diarrhea, abdominal pain, anaphylaxis, shock, or pulmonary edema. Acute hemolytic reactions with hemoglobinemia and hemoglobinuria result from transfusions from a donor with an incompatible blood type. DIC may accompany severe acute hemolysis. One should discontinue the transfusion immediately and administer supportive therapy. Intravenous crystalline fluids improve peripheral circulation and maintain renal perfusion. NSAIDs may decrease inflammatory reactions.

Febrile reactions are not uncommon during or immediately after transfusions and may result from incompatible leukocyte or platelet antigens or presence of pyrogens in the transfused blood. One should discontinue transfusions if clinical signs are severe. NSAIDs may help in decreasing the febrile response.

Occasionally, blood products become contaminated with bacteria or bacterial products, and their administration can result in severe septicemia/endotoxemia. Affected animals develop uncontrollable shaking, hypotension, weakness, tachycardia, tachypnea, and collapse. One should discontinue the transfusion immediately and administer supportive care and should culture the blood being administered. A Gram stain may reveal bacteria if contamination is severe. One should institute appropriate antibiotic therapy. NSAIDs may help in alleviating the adverse effects of endotoxin.

More delayed reactions to transfusion include transmission of infectious diseases and allosensitization of the recipient. One should test all donor horses regularly for EIAV. Other infectious agents potentially transmittable via blood transfusions include *Anaplasma phagocytophilum* and the equine herpesviruses. Mares that receive blood transfusions are at risk for producing foals that develop neonatal isoerythrolysis later in life.

12.5.2 PLASMA TRANSFUSION

Plasma transfusion is indicated in horses with hypoproteinemia sufficient to result in significant fluid loss from the blood to the extravascular space and also is indicated for foals with failure of passive transfer (discussed previously in the text), replacement of some coagulation factors (II, V, VII, X, XIII), reversal of warfarin toxicity, endotoxemia/septicemia, and in some cases of DIC. Selection of donor animals, administration of plasma, and potential adverse reactions are similar to those described for whole blood transfusions. One may estimate the volume (in milliliters) to be administered to a hypoproteinemic horse from the following formula:

$$\text{body mass (kg)} \times \text{blood volume (ml/kg)} \times \frac{(\text{albumin desired} - \text{albumin observed})}{\text{albumin concentration of donor}}$$

Plasma volume in adult horses is estimated as 48 ml/kg.[366] In neonates, plasma volume is approximately 95 ml/kg, decreasing to 62 ml/kg at 4 weeks, 53 ml/kg at 12 weeks, and adult values by 4 to 6 months of age.[367] The observed increase in plasma protein after plasma transfusions is often not as great as would be predicted from this formula and most likely is caused by equilibration of administered blood proteins between intravascular and extravascular spaces. 760

761

Plasma from suitable donors is commercially available. Large equine practices may consider the purchase of plasmapheresis equipment, capable of economically preparing large quantities of pure plasma. One also may prepare plasma by allowing erythrocytes in whole blood to settle by gravity or, preferably, by centrifugation. One then removes plasma in an aseptic manner and administers it through an intravenous system with an in-line filter.

12.5.3 BLOOD COMPONENT THERAPY

Continuous-flow centrifugation hemapheresis has been used extensively in human medicine to produce relatively pure blood components for administration to patients needing replacement of one specific blood constituent. This technique is being used increasingly in veterinary medicine and is the preferred method for equine plasma collection. Blood removed from one jugular vein of a donor horse circulates in a closed loop through the blood separation device with collection of desired blood components and return of unwanted components to the donor via the opposite jugular vein.[369,370] By altering the centrifugal force of the collection device, one may collect plasma, RBCs, leukocytes, or platelets preferentially.[371]

Collection of leukocyte and platelet-rich fractions from horses has been described.[369,371] Platelet transfusions may be indicated in selected horses with thrombocytopenia. Leukocyte transfusions have been beneficial in septic human neonates, and the feasibility and efficacy of granulocyte transfusions in the equine neonate have been investigated.[371,372]

13.1 13.1—Examination for Disorders of the Gastrointestinal Tract

Jennifer L. Davis

Samuel L. Jones

13.1.1 Physical Examination

Examination of patients with disease of the gastrointestinal tract must include evaluation of the metabolic and cardio vascular status of the patient, because acute conditions of the proximal or distal intestinal tract have the potential to lead to endotoxemia and sepsis. Examination of the cardiovascular system (heart, peripheral pulse, and mucous membranes), lungs, and abdomen is essential to detect clinical signs of systemic inflammation from endotoxemia, coagulation disorders, dehydration, ileus, shock, and other abnormalities resulting from injury to the small or large intestine. Chapter 13.7 covers clinical signs of systemic inflammation from endotoxemia and sepsis.

One performs the physical examination of the abdomen primarily by auscultation, transabdominal ballottement, and transrectal palpation. Abdominal distention often indicates distention of the large intestine; however, small intestinal distention also can cause visible abdominal distention if a large proportion of the small intestine is involved. One can perform abdominal palpation in neonatal foals; after several weeks of age, however, the abdominal wall is too rigid to allow effective palpation of intraabdominal structures.

Abdominal auscultation is particularly useful for assessing the motility of the large intestine. Progressive motility of the small intestine, conversely, is difficult to distinguish by auscultation from nonprogressive motility. The distinct character of the borborygmi produced during propulsive contractions of the cecum and ascending colon allow evaluation of the frequency and strength of retropulsion and propulsion. Propulsive contractions of the cecum and ventral colon occur every 3 to 4 minutes and give rise to prolonged rushing sounds heard over long segments of intestine. Retropulsive sounds presumably are similar to propulsive sounds, but they occur less frequently. The distinction of propulsion from retropulsion is not important clinically because both types of contractions signify normal motility. Inter- and intrahaustral mixing contractions produce nonspecific sounds of fluid and ingesta movement that are difficult to distinguish from other borborygmi, such as small intestinal contractions or spasmodic contractions.[1]

Auscultation over the right flank and proceeding along the caudal edge of the costal margin toward the xiphoid allows evaluation of the cecal borborygmi. Auscultation over a similar area on the left side allows evaluation of the pelvic flexure and ascending colon. Typical progressive borborygmi heard every 3 to 4 minutes on both sides of the abdomen indicate normal motility of the cecum and ascending colon. Less frequent progressive sounds may indicate a pathologic condition of the large intestine or may result from anorexia, nervousness (sympathetic 769
tone), or pharmacologic inhibition of motility (i.e., α_2-adrenergic agonists such as xylazine).[2-4] Absolute absence 770
of any auscultable borborygmi suggests abnormal motility and indicates ileus resulting from a serious pathologic

condition but is not specific to any segment of the intestine.[3,5] If borborygmi are audible but progressive sounds are not detectable, determining whether a significant abnormality exists is difficult.[5]

Borborygmi heard more frequently than normal may result from increased motility following feeding; from excessive stimulation from irritation, distention, or inflammation; or after administration of parasympathomimetic drugs such as neostigmine. Large intestinal motility increases in the early stages of intestinal distention regardless of the site.[6] Mild inflammation or irritation of the large intestinal mucosa also can stimulate motility.[3] Parasympathomimetic drugs stimulate contractions and auscultable borborygmi in the large intestine; however, an increase in parasympathetic tone may result in segmental contractions, which actually inhibit progressive motility.[2]

One can detect sand or gravel in the large intestinal ingesta by auscultation behind the xiphoid process. One can hear sand or gravel particles grinding together during progressive contractions of the ascending colon. The presence of sand in the ingesta becomes clinically detectable by auscultation or fecal sedimentation before the amount of sand is enough to produce clinical signs of pain or irritation (diarrhea).[7] If progressive contractions are audible without hearing sand sounds, clinically important quantities of sand likely are not present. If the frequency of progressive contractions is low or absent, detecting sand by auscultation is difficult.

Percussion of the abdomen during auscultation can reveal gas in the large intestine. The characteristic ping produced by simultaneous digital percussion and auscultation over a gas-filled viscus often is associated with abnormal accumulation of gas under pressure. This technique is particularly useful in foals, ponies, and Miniature horses because of the limitations of palpation per rectum.

One can use transabdominal ballottement to detect large, firm masses or an abnormal volume of peritoneal fluid. The usefulness of this technique is usually limited to animals too small to palpate per rectum. One can detect soft tissue masses or fetuses by bumping the structures with a hand or fist. If excessive peritoneal fluid is present, one can generate a fluid wave by ballottement; however, this technique is not as useful in horses older than 4 weeks because the abdominal wall is rigid.

Transrectal palpation is the most specific physical examination technique for investigation of intestinal disease and is particularly valuable when evaluating obstructive diseases.[8,9] The primary objectives of transrectal palpation are to assess the size, consistency, and position of the segments of the large intestine; to determine the presence of any small intestinal distention; and to detect intraabdominal masses. Evaluation of the wall thickness and texture and the mesenteric structures (blood and lymphatic vessels and lymph nodes) also may aid in diagnosis of large intestinal disease. The interpretation of transrectal palpation findings in light of clinical signs and laboratory results is an important diagnostic aid for developing appropriate treatment strategies for intestinal diseases manifested by abdominal pain.

Enlargement of one or more segments of large intestine detected by transrectal palpation provides evidence of obstruction at or distal to the enlarged segment. By systematically evaluating each segment, one may determine the site of obstruction. Obstruction of the pelvic flexure, for instance, results in enlargement of the pelvic flexure and ventral colon, but the dorsal and descending colons are of normal size. Enlargement of a segment of the large intestine usually is accompanied by abnormal consistency of the contents. One may distinguish accumulation of gas, fluid, or ingesta and may detect foreign bodies in palpable segments. Accumulation of gas and fluid infers complete and acute obstruction, whereas accumulation of ingesta infers chronic and incomplete obstruction. Accumulation of fluid usually indicates ileus. One must evaluate the consistency of the contents in light of the size of the segment; ingesta in the ventral colon of a dehydrated patient may be firm, but the size of

the ventral colon will be normal. Conversely, if the ingesta is firm because of a distal obstruction, the ventral colon will be enlarged.

Displacement of a segment of the large intestine may create an obstruction detectable by enlargement of the segment and accumulation of gas and fluid, even if the site of obstruction is not palpable. Torsion of the ascending colon at the sternal and diaphragmatic flexures results in acute accumulation of gas and fluid proximal to the torsion, causing distention of the left dorsal and ventral colons. Depending on the degree of torsion, the position of the ventral and dorsal colons may not be significantly abnormal. Displacement of a segment of large intestine often results in incomplete obstruction, and the diagnosis relies solely on detection of the displaced segment in an abnormal position. The position of the displaced segment may not be palpable, and the diagnosis then relies on the inability to find the segment in a normal position. One must take care to ensure that the segment that appears to be displaced is not in a normal position but has become too small to palpate from a decrease in the volume of ingesta. The cecum, right dorsal and ventral colons, pelvic flexure, and descending colon are palpable in most horses. One should palpate the nephrosplenic space to detect the presence of intestine, usually pelvic flexure, entrapped within the ligament.

770

771

Small intestine is not normally palpable in the horse. Distention is an indicator of ileus with gas or fluid retention, usually following a strangulating or nonstrangulating obstruction. Strangulating obstructions result from conditions such as volvulus or torsion, lipoma, or entrapments. Such conditions often are accompanied by severe pain, dehydration, peritoneal fluid changes, and a varying degree of gastric fluid accumulation. The small intestine in these cases is turgid and firm on palpation. One should assess the mesentery and wall thickness as for large intestinal disorders. Careful palpation of the inguinal rings in stallions with small intestinal distention is crucial for determining inguinal herniation.

Evaluation of the wall thickness and mesenteric vessels can reveal venous congestion (mural edema and enlarged blood and lymphatic vessels) or inflammation (mural edema with normal vessels). Disruption of arterial blood flow does not cause venous congestion, but the arterial pulse is not detectable. Mesenteric tears may not be palpable, but the entrapped ischemic intestinal segment may be thickened with edema. One may detect acute or chronic inflammation with cellular infiltration of the intestinal wall as thickening of the wall without edema and also may note enlargement of mesenteric lymph nodes. One should interpret abnormalities in the wall or vessels in light of the size, consistency, and position of the segment of intestine and the clinical signs.

Several conditions involving small intestinal strangulating lesions do not necessarily cause abnormal rectal examination findings until the disease has been present for an extended time. These conditions include diaphragmatic herniae and epiploic foramen entrapments. Peritoneal fluid analysis may be normal in these cases as well because the fluid is trapped in the thorax or in the cranial abdomen. Surgery is usually necessary for diagnosis.

Nonstrangulating causes of small intestinal distention can be divided further into intraluminal and extraluminal obstructions. Ileal impactions are probably the most common cause of intraluminal obstructions, and on rare occasions one can palpate the impaction in the upper right quadrant, near the ileocecal opening. Intraluminal masses caused by lymphoma, eosinophilic enteritis, foreign bodies or ascarid impactions often lead to small intestinal distention and are usually indistinguishable from one another based on palpation alone. Small intestine in these cases can be moderately to severely distended, depending on the degree of obstruction. Extraluminal obstructions include abdominal masses, abscesses or tumors, and large colon displacement. One always should palpate the rest of the abdomen carefully to help rule out these causes.

Some cases of small intestinal distention result from a physiologic rather than a mechanical obstruction. Ileus may result postoperatively or following inflammatory diseases of the bowel (proximal enteritis) or peritoneal

cavity (peritonitis). The bowel is usually mildly to moderately distended and almost always is accompanied by significant amounts of accumulated gastric fluid.

The small colon is easily distinguishable by the presence of normal fecal balls and an antimesenteric band. In cases of impaction of the small colon, a long, hard, tubelike structure is present in the caudal abdomen, and the band is palpable along the length. Fluid stool is often present in the rectum in these cases, as is tenesmus.

One can detect and carefully evaluate rectal tears by palpation. One can detect mural masses in palpable segments of intestine or mesentery; however, if a mass causes obstruction, one can detect the result of the obstruction in proximal segments of intestine even if the mass is unreachable. Palpation of the mesenteric vessels may reveal thickening and thrombosis, which can lead to ischemia or infarction.

One can perform visual inspection of the mucosa of the rectum and descending colon with a speculum or flexible endoscope and also can evaluate rectal tears or perforations, mural masses, strictures, or mucosal inflammation. One also can perform guided biopsy of the mucosa or masses. The obvious limitations are the amount of fecal material interfering with the examination and the distance of the lesion of interest from the anus. These techniques offer little advantage over palpation in many cases unless the patient is too small to palpate.

Examination of the oral cavity in cases of dysphagia or weight loss is a necessary part of the physical examination. One should adequately sedate the horse and should use a full-mouth speculum to allow palpation and visualization of all parts of the oral cavity. One should examine the area for abnormal dentition, foreign bodies, fractures, abscesses, and ulceration.

The presence of fluid accumulation in the stomach indicates a decrease or absence in propulsive motions of the small intestine or obstruction of gastric outflow. Decreased small intestinal motility may result from a functional or mechanical blockage. Masses, feed impactions, or strictures in the pylorus or in the proximal duodenum may obstruct gastric outflow. One routinely assesses fluid accumulation in the stomach by siphoning off the gastric contents with a nasogastric tube and examining the fluid for amount, color, and any particular odor. Normal fluid is green and may contain foamy saliva. The volume obtained by gastric lavage is usually less than 4 L.

Large volumes of fluid (>8 to 10 L) accumulate in the stomach of horses with proximal enteritis, and the fluid is foul smelling and often has an orange to yellow discoloration. If one suspects proximal enteritis, one can submit the fluid for culture and Gram staining. *Salmonella* sp. and *Clostridium* sp. have been cultured in some cases. Patients with postoperative ileus also frequently accumulate large amounts of gastric fluid. Horses with 771
strangulating obstructions or luminal obstructions often accumulate moderate amounts of gastric fluid, but the 772
amount is generally less than in horses with proximal enteritis or postoperative ileus. Hemorrhage in the gastric fluid usually indicates devitalized small intestine, stomach wall, or severe gastric ulceration. Fluid with large amounts of food material often indicates a gastric impaction, and one should lavage the stomach until obtaining no more ingesta. Horses and foals with chronic gastric ulceration in the glandular mucosa of the stomach or in the duodenum may develop strictures and have fluid accumulate in the stomach. Endoscopy or contrast radiography aids in diagnosing gastric outflow obstruction.

13.1.2 Clinical Pathology

Evaluation of the hemogram is essential when one assesses conditions of the gastrointestinal tract. However, hematologic alterations associated with diseases of the gastrointestinal tract are often nonspecific, reflecting systemic response to inflammation, endotoxemia, or sepsis. Neutrophilic leukocytosis and normochromic, normocytic anemia with or without hyperfibrinogenemia commonly are associated with chronic inflammatory conditions of the intestine. Anemia from chronic blood loss occurs infre quently in adult horses because of the

large iron stores and high concentrations of iron in their diet; usually anemia follows chronic inflammation, as do alterations in the leukon and plasma fibrinogen concentrations. Plasma protein concentrations vary depending on gastrointestinal losses of albumin and globulin and elevation of globulin concentration from antigenic stimulation. Protein-losing enteropathies may manifest predominantly as a hypoalbuminemia or may have a concurrent hypoglobulinemia. Immunoglobulin quantification can be useful in selected cases; immunosuppression with low immunoglobulin M concentration has been shown to occur in some cases of lymphosarcoma.[10] Parasitic infections, especially strongylosis, may be characterized by elevated serum immunoglobulin G(T) concentration.[11]

Significant alterations of the hemogram do not accompany acute disease of the intestine unless severe inflammation, dehydration, endotoxemia, or sepsis is present. During the early stages of endotoxemia, elevations in circulating concentrations of inflammatory mediators, epinephrine, and cortisol produce characteristic changes in the hemogram. Leukopenia, with neutropenia and a left shift, toxic changes in the neutrophil cytoplasm, and lymphopenia occur commonly.[12] Hemoconcentration and hyperfibrinogenemia are also common. Thrombocytopenia and other coagulopathies are also features of endotoxemia. Indeed, thrombocytopenia may be the earliest indicator of sepsis.[13] Endotoxemia and circulating mediators of inflammation activate the coagulation cascade, causing a hypercoagulable state that can lead to consumption of coagulation factors and coagulation defects manifested as elevated prothrombin time, partial thromboplastin time, fibrin degradation products, and bleeding time, and reduced activity of antithrombin III.[14–16] Neutrophilic leukocytosis occurs during the later stages of endotoxemia.[14]

The most common serum biochemical abnormalities with diseases of the large or small intestine are electrolyte imbalances. Serum calcium concentrations are often low with strangulating obstructions and acute inflammatory diseases.[17] Inflammation of the mucosa can disrupt electrolyte fluxes severely. Diarrhea or gastric reflux greatly exacerbates the loss of sodium, potassium, calcium, magnesium and bicarbonate. Ischemia of the intestine causing hypoxia and cellular damage may be reflected by an elevated serum phosphate concentration resulting from phosphate leakage from damaged cells.[18] Ischemia and cellular hypoxia in any segment of the intestine also causes a shift in energy metabolism to anaerobic glycolysis, resulting in increased production of lactate and elevated serum lactate concentration. Reduced perfusion of peripheral tissues from hypotensive shock and intestinal ischemia can cause elevations in serum lactate. However, obstruction of the intestine during ischemia may result in absorption of lactate from the lumen.[19,20] Anion gap is an indirect measurement of organic acid production during states of tissue hypoxia and is a reasonable estimate of serum lactate concentration.[20] Metabolic acidosis may accompany lactic acidemia, but an inconsistent association exists between the two, especially when mixed acid-base imbalances are present.[20,21] Elevations of hepatic enzymes, specifically γ-glutamyltransferase, may occur with large colon displacements, duodenal strictures, or anterior enteritis.

Relative polycythemia from hemoconcentration or splenic contraction and changes in red blood cell deform ability from hypoxia or hypocalcemia may increase blood viscosity. Blood viscosity increases in patients with acute obstructive disease. Hyperviscosity reduces perfusion of capillary beds, thereby exacerbating ischemia and tissue hypoxia.[22] Hyperviscosity is one manifestation (along with lactic acidemia, coagulopathies, and clinical signs of shock) of the pathophysiologic events that take place during acute inflammatory or vascular injury to the large intestine. Laboratory tests designed to reflect the systemic effects of endotoxemia, ischemia, sepsis, and shock are important to design therapeutic strategies, and monitor response to therapy.

13.1.2.1 EXAMINATION OF PERITONEAL FLUID

Abdominocentesis and analysis of peritoneal fluid (PF) is a diagnostic technique performed on many patients with disease of the gastrointestinal tract. One can quantitate cytologic examination of PF; white blood cell and red blood cell counts; protein, fibrinogen, lactate, phosphate, and glucose concentrations; lactate dehydrogenase, creatine kinase, and alkaline phosphatase activity; and pH. The results of PF analysis may help establish a specific diagnosis but more importantly may reflect inflammatory, vascular, or ischemic injury to the intestine requiring surgical intervention. 772 773

PF reflects a sequence of events that takes place during acute vascular injury to the intestine. The PF protein concentration first increases, followed by an increase in the red blood cell count and fibrinogen concentration. A transudative process resulting from vascular congestion and increased endothelial permeability allows small macromolecules (albumin) to escape into the PF, followed by larger macromolecules (globulin and fibrinogen), and finally diapedesis of cells (red blood cells, then white blood cells).[23,24] If ischemic inflammation of the intestine and visceral peritonitis occur, an exudative process ensues. Severe inflammation of the intestine and visceral peritoneum causes large quantities of protein and white blood cells, primarily neutrophils, to escape into the PF.[24] As damage to the bowel progresses, the protein concentration and red blood cell and white blood cell counts continue to rise. As the degree of irreversible damage to the intestine increases, the PF characteristics become more exudative.[23,24] Eventually, bacteria begin to translocate across the intestinal wall and appear in the PF as the mucosal barrier breaks down. Neutrophils predominate, and their cytoplasm becomes granulated, and Döhle bodies often are visible. If perforation occurs, bacteria and particles of ingesta appear in the PF, and the neutrophils become degenerate, that is, pyknotic, with karyorrhexis, karyolysis, and smudge cells.[23]

Elevated PF protein concentration is a sensitive indicator of early inflammation, whereas elevated red blood cell counts in the presence of normal white blood cell counts suggest vascular damage without significant tissue ischemia.[24] Elevation of the white blood cell count usually indicates severe tissue inflammation or intestinal injury.[25] The gross color of the PF can be helpful in detecting injury and necrosis of the intestine. A serosanguinous appearance indicates vascular injury, whereas orange or brown-red indicates necrosis with the release of pigments such as hemosiderin. Serial samples of PF are most useful in determining the nature and extent of damage to the intestine, but in many cases of ischemia, irreversible tissue damage has occurred by the time PF abnormalities appear.

Tissue hypoxia and ischemia cause a rapid elevation of PF lactate dehydrogenase, creatine kinase, and alkaline phosphatase activity and lactate concentration.[19,20,26] Phosphate concentration increases when cellular disruption occurs.[18] PF enzyme activities, phosphate, and lactate concentration increase faster and higher than serum activities.[18–20,26] PF pH and glucose concentration tend to decrease during intestinal ischemia, but not as low as in septic peritonitis.[27] Although biochemical alterations may provide early indicators of intestinal ischemia and necrosis, they are nonspecific and offer no advantage over conventional methods of PF analysis in many cases. PF alkaline phosphatase has been shown to arise predominantly from degenerating white blood cells, and elevations of other enzyme activities may occur with many inflammatory diseases.[26] Thus the specificity of many tests run on PF is questionable. However, in selected cases in which conventional PF analysis and physical examination do not provide sufficient information to develop a treatment plan, biochemical analysis of the PF may be useful.

Cytologically examined cells of the PF may reflect chronic inflammatory conditions of the large intestine, especially eosinophilic or lymphocytic processes.[28] Infectious and inflammatory conditions often cause increases in the neutrophil count and may be indistinguishable unless bacteria are visible. One also may detect neoplastic diseases by PF examination. Chronic infection and inflam mation may be associated with elevated PF protein and fibrinogen concentrations. Culture of PF usually is required to distinguish bacterial infections from noninfectious inflammation unless bacteria are visible on cytologic examination. However, culture of PF is often unrewarding because factors that are found in inflammatory PF inhibit bacterial growth, and leukocytes phagocytose many bacteria in the PF.[29] Decreases in PF glucose concentrations (<30 mg/dl) and pH (<7.3) are early indicators of a septic process. The glucose concentration and pH in the PF should approximately equal the blood glucose concentration and pH. A PF fibrinogen concentration greater than 200 mg/dl also indicates bacterial infection.[30]

13.1.2.2 FECAL EXAMINATION

Gross examination of the feces can provide information about digestion and transit time in the large intestine. Large fiber particles in the feces represent poor mastication or poor digestion in the large intestine. Small, mucus-covered, hard fecal balls indicate prolonged transit through the descending colon, whereas increased fluidity implies decreased transit time. Feces containing sand or gravel are not necessarily abnormal. However, a significant amount of sand implies that large quantities are present in the colon. Frank blood indicates substantial bleeding into the distal colon (right dorsal colon and/or small colon) from mucosal damage.

Laboratory analysis of the feces is performed frequently in cases of diarrhea. Fecal cytologic examination and 773
tests for occult blood detect mucosal inflammation, erosion, or ulceration. Severe inflammatory diseases in 774
human beings, invasive bacterial infections in particular, have been shown to increase the shedding of leukocytes in the feces. A higher percentage of horses with salmonellosis and diarrhea have fecal leukocyte counts greater than 10 cells per high power field than horses with negative fecal cultures for *Salmonella*. These results suggest that high fecal leukocyte counts indicate salmonellosis in horses with diarrhea. However, the specificity of this test is probably low. Low fecal leukocyte counts do not rule out salmonellosis.[31]

Fecal occult blood tests detect blood in the feces, presumably from erosion or ulceration of the mucosa, but do not distinguish the source of the blood. Large volumes of blood (1 to 2 L) given by nasogastric tube were required to produce a positive test for occult blood in the feces, but the amount of blood originating from the large intestine required to produce a positive test is unknown. A positive test implies significant hemorrhage into the gastrointestinal tract. Newer, more sensitive tests detect not only occult blood but also degraded blood and may be useful to determine the site and quantity of blood loss.[32] A positive test implies significant hemorrhage into the gastrointestinal tract.

Bacteriologic examination of the fecal flora has been used to quantitate specific bacterial species in the feces of horses with diarrhea. Quantitation of clostridial species may be beneficial in diagnosing clostridial infection of the large intestine.[33] Tests to detect clostridial toxins in intestinal contents or feces are important to determine whether clostridia cultured from the feces are causing disease. The most common bacterial pathogens isolated from the feces of horses are *Salmonella* and *Clostridium*. The number of *Salmonella* organisms isolated from the feces of horses with clinical salmonellosis is usually higher than from horses with asymptomatic infections. However, the volume of feces in many cases of acute diarrhea is high, and the concentration of *Salmonella* organisms may be lower than would be expected, accounting for many false-

negative fecal cultures. The sensitivity of fecal cultures for detecting *Salmonella* infection may be as low as 20%. Culture of five consecutive daily fecal samples is recommended to increase the sensitivity of the test. Because salmonellae are intracellular organisms, culture of rectal scrapings or a rectal biopsy sample, along with fecal material, may increase the sensitivity of culture for detecting *Salmonella* infection to 50%.[34] One can perform a polymerase chain reaction assay on fecal samples to detect DNA from *Salmonella* sp. The polymerase chain reaction test is more sensitive than culture and is frequently positive in clinically normal horses that continuously shed small amounts of bacteria. Polymerase chain reaction or immunologic tests also may detect *Clostridium perfringens* and *C. difficile* exotoxins in the feces.

Qualitative fecal examination is a technique to detect nematode and cestode ova, protozoan oocysts, parasitic larvae, and protozoan trophozoites. A direct smear of fecal material is a rapid method to screen feces for ova and oocysts, to detect parasite larvae and trophozoites, and to observe motility of ciliates and parasite larvae. Fecal flotation is a more sensitive technique for isolating and detecting ova and oocysts because the eggs are concentrated from the sample. Zinc sulfate and sucrose solutions are often used to concentrate less dense ova and oocysts. Zinc sulfate produces less distortion of trophozoites and larvae than sucrose solutions. Fecal sedimentation is particularly appropriate for ciliates, *Giardia,* and trichomonads. Quantitative techniques such as the Cornell-McMaster method allow one to estimate the number of eggs per gram of feces and are most appropriate in monitoring parasite control programs.[35]

13.1.3 Radiography

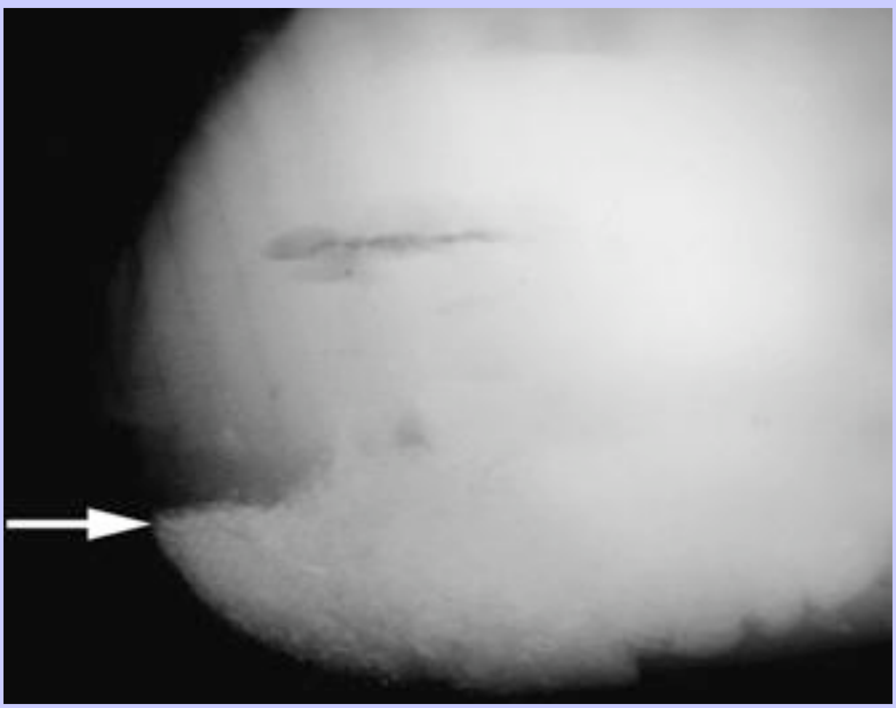
Survey radiography of the normal esophagus is usually unrewarding but may be useful in horses with esophageal obstructions to determine the extent and location of the obstruction. One may detect foreign bodies or soft tissue masses, and in cases of esophageal rupture, one may see free air and ingesta in the tissues surrounding the esophagus and may observe pneumomediastinum.[36] Thoracic radiographs may be necessary to detect intrathoracic esophageal obstructions, megaesophagus, or cranial mediastinal masses causing extraluminal obstruction. One may use barium swallows or double-contrast esophagrams after resolution of the obstruction to determine whether a stricture or diverticulum or other underlying disorder is present.[37] Barium sulfate is the usual contrast medium and can be administered orally via a dose syringe or by nasogastric tube (50 to 100 ml of a 40% barium sulfate suspension or barium paste). Oral administration is preferred for evaluation of swallowing and lesions in the proximal esophagus. Administration of contrast using a nasogastric tube (preferably cuffed) allows for delivery of larger volumes of barium (up to 500 ml) but should be performed without sedation if possible. One can follow administration of contrast material with air insufflation to create a double-contrast effect. If one suspects a rupture of the esophagus or if the likelihood of aspiration of the contrast material is high, one should use iodinated organic compounds in an aqueous solution as contrast material.[36] Contrast radiography may be the most definitive method for the diagnosis of primary megaesophagus or other functional disorders such as autonomic dysautonomia (grass sickness) affecting the esophagus.[37] One should take care when interpreting esophageal radiographs if the horse is sedated. Acepromazine or detomidine administration causes 774
esophageal dilation in normal horses, especially after passage of a nasogastric tube.[38] 775

Radiography of the adult equine abdomen is an effective technique in detecting radiodense material in the large intestine, such as enteroliths, sand, and metallic objects.[39,40] One survey demonstrated that radiography has 76.9% sensitivity and 94.4% specificity for diagnosing enterolithiasis.[39] Radiography also can be a useful tool for detecting sand accumulation in the colon that causes diarrhea or impactions (Figure 13.1-1) and for monitoring resolution in medically treated horses.[41] The large size and density of the adult abdomen precludes evaluation of soft tissue structures because the detail and contrast of the radiographs are usually poor. One is

more likely to obtain diagnostically useful abdominal radiographs from small ponies and miniature horses than from full-size adult horses. Accumulation of gas is visible on radiographs of adult horses, but distinguishing normal intestinal gas from obstruction is often difficult. Horses should be fasted for 24 to 48 hours to reduce the amount of ingesta in the large intestine before radiography.

Abdominal radiography is more useful in foals than in adult horses. Radiographs are more detailed and contrast can be good. Radiographic evidence of gas distention in the large intestine may indicate large intestinal obstruction, and radiographic signs of displacement are often diagnostic. One may diagnose impactions, intussusceptions, foreign bodies, and other disorders with the aid of radiography. Functional ileus may be difficult to distinguish from mechanical obstruction.[42,43] Administration of contrast (barium sulfate 30% at 5 ml/kg) via nasogastric tube increases the diagnostic capabilities of radiography.[44] Gastric ulceration also is recognizable with contrast radiography in the foal, although this is not as accurate a method as endoscopy.[45] Contrast administered retrograde via a 24-F Foley catheter inserted into the rectum at a dose of up to 20 ml/kg has excellent potential for diagnosing disorders of the small colon, transverse colon, and large colon in foals.[46]

Figure 13.1-1 Radiograph of the cranioventral abdominal region of a weanling colt with diarrhea. The radiopaque accumulation of sand *(arrow)* in the sternal flexure of the ventral colon is notable.



13.1.4 Ultrasonography

Ultrasonographic evaluation of the abdomen can add valuable information in cases of acute or chronic gastrointestinal disease. Examination of the adult horse requires a 2.5- to 5.0-MHz transducer at minimum. One

may use sector, linear, or curved linear transducers. Clipping of the hair over the area to be examined, along with the application of isopropyl alcohol and ultrasound coupling gel, enhances evaluation.

To evaluate the abdomen adequately, one must know the anatomic location and normal appearance of the individual organs. In the left cranial abdomen, one can assess the greater curvature of the stomach between the eleventh and thirteenth intercostal space, and one can use the spleen and the large splenic vein as landmarks. Cases of gastric dilation from gas or impaction appear as an enlargement of the viewing area to cover greater than five rib spaces.[47] One also can evaluate the stomach for intramural or extramural masses such as abscesses or for squamous cell carcinoma.[48] The lesser curvature is not routinely visible.

Assessment of the small intestine should include evaluation for changes in thickness, motility, location, and visibility. One may find small intestinal loops easily in the left lower quadrant of the abdomen, but these normally are visible in other locations. One can visualize the duodenum consistently on the right side of the abdomen deep to the liver in the tenth to twelfth intercostal space or deep to the right kidney at the fifteenth to sixteenth intercostal space. Mural thickening (>4 mm) may occur in cases of infiltrative or proliferative diseases, postoperative cases, enteritis, and paralytic or mechanical ileus. Thickening of the small intestinal wall in foals, with or without the presence of gas shadows within the wall, should raise suspicions of clostridial enteritis.

One can assess motility by monitoring a specific area for contractions over time. Ultrasonography is an accurate method of distinguishing strangulating versus nonstrangulating disorders of the small intestine. Strangulated small intestine has thicker small intestinal walls and larger intestinal diameter than in nonstrangulating disorders. Strangulating lesions have decreased motility in the incarcerated segments with normal motility elsewhere.[49] Cases of paralytic ileus or nonstrangulating obstruction have a diffusely decreased peristalsis, but not to the 775

776 degree observed with strangulating lesions.[47,49] One may diagnose some specific lesions of the small intestinal tract using ultrasonography. One may see ascarids in foals in cases of ascarid impaction[47] and epiploic foramen entrapments as edematous loops of small intestine found in the right cranial abdomen.[50] One may note small intestinal intussusceptions as targetlike lesions when viewed in cross sections.[51] The presence of bowel loops, stomach, or liver in the thoracic cavity indicates the presence of herniation through the diaphragm and should be confirmed using radiography or surgical exploration.

Evaluation of the large intestine may be difficult because of the large amounts of gas within the lumen. However, certain disorders are readily identifiable via ultrasonography. One can assess the nephrosplenic ligament area for bowel entrapment in the left paralumbar fossa. In cases of entrapment, the spleen will be pulled away from the body wall and fluid or gas shadows will be observable dorsal to the spleen,[52] obscuring the kidney, which is normally adjacent and abaxial to the spleen. Small colon, small intestine, or pneumoperitoneum also may produce a gas shadow and obscure the kidney from view.[47]

Sand impactions may appear as hyperechoic bands on the ventral abdominal wall.[47] One may see ileocecal and cecocolic intussusceptions in the upper right paralumbar fossa.[53] In cases of colitis, large, fluid-filled colons may be visible with or without intramural edema. One can find the right dorsal colon consistently abaxial to the liver, within the right thirteenth to fifteenth intercostal space and may be thickened (>5 mm) in cases of right dorsal colitis.

Evaluation of the abdomen always should include assessment of the peritoneal space for any evidence of an increased amount of PF or increased cellularity of the fluid as indicated by an increase in echogenicity. Ultrasonography also can be useful in determining the ideal location for abdominocentesis. One also should evaluate the liver, kidneys, and spleen. One may detect choleliths, nephroliths, masses, abscesses, or enlargement

of any of these organs. Abscesses or tumors not associated with visceral organs may be difficult to visualize and interpret via ultrasonography.

13.1.5 Nuclear Scintigraphy

Although more commonly used to diagnose lameness and musculoskeletal problems, nuclear scintigraphy has several uses for evaluation of the gastrointestinal tract. Scintigraphy is now available at most universities and many private referral hospitals. One must use proper isolation protocols and waste disposal techniques strictly.

The procedure requires special gamma cameras and the injection of radioactive materials into the bloodstream. One can use one of two methods: injection of technetium-99m methylene diphosphonate (^{99m}Tc-MDP) directly into the blood or injection of ^{99m}Tc-labeled leukocytes. Labeling of leukocytes involves aseptically collecting heparinized blood samples, isolating the buffy coat, and mixing those leukocytes with a radioactive dye (^{99m}Tc hexamethylpropyleneamine oxime, or ^{99m}Tc-HMPAO) in vitro.[54] One then reinjects the labeled leukocytes and obtains images. The principle of nuclear scintigraphy then lies in increased uptake of the dye or the white blood cells into areas of inflammation.

One of the most common uses of nuclear scintigraphy in evaluating the gastrointestinal tract is diagnosis of dental disease. Scintigraphy using ^{99m}Tc-MDP proved to be more sensitive in cases of dental disease than was radiography. Scintigraphy was slightly less specific, however, and therefore should be used with radiography or computed tomography for ultimate accuracy.[55] Scintigraphy using radiolabeled white blood cells can support a diagnosis of right dorsal colitis in the horse.[40] Images taken of the abdomen 20 hours after injection showed an increased linear uptake of leukocytes in the region of the right dorsal colon in horses with right dorsal colitis compared with normal horses. This technique also may prove useful for diagnosing intraabdominal abscesses in the horse. Other uses of nuclear scintigraphy include evaluation of metastasis of abdominal tumors to bony areas, assessment of biliary kinetics, and determination of gastric emptying times.[56–58]

13.1.6 Endoscopy

Endoscopic examination of the gastrointestinal tract begins with evaluation of the pharyngeal area by examination for any signs of collapse or dysfunction. One should evaluate the ability of the horse to swallow. The floor of the pharynx should be clean and free of feed material and foreign bodies. One can examine the oral cavity with the horse under heavy sedation or anesthesia and with the help of a full-mouth speculum. One can examine the teeth for any irregularities, obvious cavities, sharp points, or hooks and the hard and soft palpate for completeness and any evidence of ulceration, masses, or foreign bodies.

One should use a 3-m flexible fiberoptic endoscope to examine the esophagus, which is accomplished best by passing the endoscope into the stomach and viewing the esophagus as one withdraws the endoscope while dilating the lumen with air. The esophageal mucosa normally should be a glistening, light pink color. Ulceration can occur with cases of choke, reflux esophagitis or in horses that have had an indwelling nasogastric tube. 776
Erosions may be punctate, linear, or circumferential. One should evaluate carefully for any ulcers to ensure that 777
no areas of perforation through the entire thickness of the esophageal wall exist. Distinguishing normal peristaltic contractions from areas of stricture requires observation of the area and its motility over time. One also may note diverticula as outpouchings of the mucosa, sometimes associated with a stricture distally. Megaesophagus, although rare, appears as a generalized dilation of the esophagus. One may detect food or foreign body impactions of the esophagus via endoscopy. One always should reevaluate the esophagus after

removing any obstruction to detect the presence of complications (ulceration, rupture) or initiating causes (strictures, diverticula, and masses).

A 3-m flexible endoscope also allows examination of the stomach. The horse should be fasted for at least 12 hours before endoscopy. One can examine the cardia and fundus easily, as well as the margo plicatus. The squamous mucosa should resemble the esophageal mucosa. The glandular mucosa should be glistening red and may have a reticulated pattern. One should carefully examine for evidence of ulceration or masses. One can obtain transendoscopic biopsy material easily from esophageal, pharyngeal, or gastric masses, and because the biopsy size will be small, one should take several samples for histopathologic examination. Pharmacologic agents (bethanechol) to empty the stomach and provide complete visualization of the entire fundic region, the pylorus, and the duodenum may be useful. For a complete description of gastroscopy and evaluation of gastric and gastroduodenal ulceration, please refer to Chapter 13.10.

13.1.7 Tests of Absorption and Digestion

D-Glucose or D-xylose absorption tests are useful in determining malabsorption of carbohydrates from the small intestine in horses. The protocol for absorption tests using either carbohydrate is similar. The horse should be fasted for 18 to 24 hours before testing. Increased periods of fasting actually have been shown to decrease absorption of d-xylose and interfere with results.[59] One administers a dosage of 0.5 to 1 g/kg of D-glucose or D-xylose via a nasogastric tube. Administration of sedatives may increase the blood glucose levels falsely and interfere with gastrointestinal transit times. One then collects blood samples to measure glucose or xylose concentrations at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. One may take additional samples up to 6 hours after dosing if the results are questionable. One should measure glucose in blood samples collected with sodium fluoride as an anticoagulant and measure xylose in samples collected in heparinized plasma.

A normal D-glucose absorption test, also known as an oral glucose tolerance test, should have a peak between 90 and 120 minutes, and this peak should be greater than 85% above the resting glucose value.[60] *Complete malabsorption* is defined as a peak less than 15% above the resting levels, and *partial malabsorption* is defined as a peak between 15% and 85% above the resting level. One must keep in mind that gastric emptying, gastrointestinal transit time, length of fasting, cellular uptake and metabolism, and endocrine function influence glucose absorption curves. Malabsorption demonstrated by the oral glucose tolerance test is sensitive but not specific. Diseases that may cause a lowered or delayed peak include infiltrative lymphosarcoma, inflammatory bowel disease (lymphocytic-plasmacytic or eosinophilic), cyathostomiasis, chronic colitis (*Salmonella* sp.), multisystemic eosinophilic epitheliotropic disease, food allergies, and small intestinal bacterial overgrowth.[61]

D-Xylose absorption tests have some advantages over the oral glucose tolerance test because xylose is not metabolized in the small intestinal mucosa and insulin does not influence its absorption. Gastric and intestinal motility, intraluminal bacterial overgrowth, and renal function still influence xylose absorption, because the kidneys clear xylose.[61] The other main drawback to d-xylose is that it is generally available only in research settings. However, xylose measurements are available at most major universities. A normal d-xylose absorption curve should peak between 20 and 25 mg/dl at 60 to 120 minutes after dosing.[62] Decreased xylose absorption can occur in horses with inflammatory bowel disease, lymphosarcoma, multisystemic eosinophilic epitheliotropic disease, cyathostomiasis, extensive small intestinal resections, and any cause of villous atrophy.[61]

Maldigestion is a common occurrence in foals with diarrhea. Bacteria (especially *Clostridium* sp.) and viruses (especially rotavirus or coronavirus) may invade and destroy the villous epithelial cells that manufacture lactase

and other disaccharidases, resulting in an inability to digest lactose. In this case, continued ingestion of the mare's milk may cause an osmotic diarrhea, which may exacerbate the underlying enterocolitis. One can perform lactose tolerance testing to assess the degree of maldigestion. One administers d-lactose at 1 g/kg as a 20% solution via nasogastric tube and measures glucose concentrations in the blood at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes. A normal curve shows doubling of glucose levels compared with baseline by 60 minutes after administration.[63]

13.1.8 Evaluation of Gastric Emptying

Assessment of gastric emptying may be useful in evaluating delayed emptying of feed or fluids from the stomach in cases of gastric and esophageal ulceration, pyloric stenosis, proximal enteritis, and postoperative ileus. 777
However, accurate measurement of gastric emptying can be difficult to assess. Several methods are currently 778
available.

Multiple diagnostic imaging techniques have been used to study gastric emptying times. One can use contrast radiography to assess gastric emptying in foals. In the normal foal, barium remains in the stomach for varying amounts of time, but a significant amount should be gone within 2 hours.[44] Gastric emptying of solid, nondigestible, radiopaque markers also has been used in adult horses and ponies, but the results were variable and unpredictable even in the normal horse.[64] Nuclear scintigraphy is used commonly in human beings to measure gastric emptying and can be used in horses where available. This technique requires oral administration of ^{99m}Tc pentenate (10 mCi), and serial images taken of the cranial abdomen. The tracer is usually not visible 60 minutes after administration in normal horses.[58]

Alternatively, if nuclear scintigraphy is not available, one can use acetaminophen absorption testing as an indirect determination of gastric emptying.[58,65] One performs this test by administering 20 mg/kg of acetaminophen orally and measuring subsequent blood values and calculating the time to reach maximum serum concentrations and the absorption constant. In human beings, the proximal small intestine absorbs almost all of the acetaminophen.[66] The median time to reach peak plasma levels using acetaminophen absorption in horses was 47.7 minutes.[58]

13.1.9 Histopathologic Examination

One often requires histopathologic examination of tissue s from the intestine to diagnose chronic inflammatory, infiltrative, or neoplastic conditions, and such examinatio n can be useful in evaluating the extent of injury after obstruction or ischemia. Rectal mucosal biopsies are easy to collect with few complications. However, to collect a full-thickness biopsy of the intestine requires a surgical approach (flank or ventral midline approach). Laparoscopy offers a safer technique to observe the large intestine and other abdominal structures.[67] One can obtain biopsies of masses, lymph nodes, mesentery, or intestinal serosa via laparoscopy and mucosal biopsies of the upper gastrointestinal tract via endoscopy.

13.1.10 Advanced Diagnostics

Other diagnostics, specifically laparoscopy and computed tomography, are available but require specialized equipment and personnel with specific training. Flexible or rigid endoscopes used for laparoscopic evaluation of the abdomen allow for visualization of visceral organs and potentially for collection of biopsy material from

masses or organs. Full-thickness biopsies of the intestines are not routinely possible through the laparoscope and usually require flank or ventral midline laparotomy. The laparoscopic procedure can be done in the standing or recumbent horse. Advantages of this technique over a flank or ventral midline celiotomy include smaller incisions, less healing time, and less procedure time. Disadvantages include the large amount of equipment needed, skill involved, and the limitation as a diagnostic modality, rathe r than a treatment.[68] Clinical applications of diagnostic laparoscopy include rectal tears, percutaneous abscess drainage, assessment of adhesions, displacements, and integrity of the serosa of various bowel segments, and biopsy of abdominal masses.[67]

Computed tomography scans are available at several universities across the country. They have been used frequently to evaluate dental disease and may be useful in evaluating tumors and masses of the head, larynx, pharynx, and proximal esophagus.[69] Computed tomography also has promise for evaluating abdominal disorders in foals. Most equipment can accommodate up to 400 lb. Restrictions to computed tomography as a diagnostic aid include expense, availability, expertise, and weight and size limitation.

13.2

13.2—Pathophysiology of Gastrointestinal Inflammation

Samuel L. Jones

The inflammatory response of the gastrointestinal tract is a mechanism ultimately aimed at eliminating pathogens, initiating tissue repair, and restoring the gastrointestinal barrier. Inflammation alters blood flow, endothelial permeability increases, cells are recruited rapidly into the tissue, plasma protein cascades are activated, and a myriad of soluble products are released that coordinate the response, trigger innate and adaptive immunity, and mobilize reparative elements. Although the cellular and vascular response and the secreted mediators of

inflammation are important for killing pathogens and limiting invasion of injured tissues by commensal organisms, they can be damaging to host cells and proteins if not tightly regulated. Thus if the inciting stimulus is not eliminated quickly, the inflammatory response itself causes significant tissue injury. The mechanism regulating inflammation has been the focus of much research to identify therapeutic targets to modulate the damage to host tissues during many gastrointestinal diseases. Recent work has provided some of the molecular and cellular details of this complex physiology and has led to novel therapeutic strategies for treating inflammation.

13.2.1 Initiation of the Inflammatory Response

13.2.1.1 EPITHELIUM

The gastrointestinal epithelium interfaces with a luminal environment inhabited by potentially hostile microbial organisms. The epithelium presents a physical barrier to invasion by the flora of the gastrointestinal tract, consisting of the apical cellular membrane, intercellular tight junctions the permeability of which is highly regulated, and a secreted layer of mucus. Breaching of the mucosal barrier by invading pathogens generates potent soluble and neural signals that initiate an inflammatory response.[1] Conceptually, the epithelium can be thought of as a sensory organ detecting pathogen invasion to trigger an appropriate host defense and reparative response.

Noninfectious mucosal injury or invasion of epithelial cells by pathogenic organisms such as *Salmonella* activates synthesis of proinflammatory chemokines (chemoattractants) by epithelial cells and triggers a robust influx of neutrophils into the tissue within hours of the damage.[1] Of the chemoattractants produced by epithelium, interleukin-8 (IL-8) has a particularly important role in initiating inflammation by recruiting neutrophils from blood[2–4] and regulating neutrophil migration through tissue matrix adjacent to epithelium.[5,6] Bacteria-derived formylated chemotactic peptides also act as potent chemoattractants that are fully capable of stimulating a robust inflammatory response in the intestine if the epithelial barrier permits the diffusion of the peptides across the mucosa.

Epithelial cells activated during infection produce cytokines such as tumor necrosis factor α (TNF-α), 780
arachidonic acid metabolites, and other proinflammatory mediators that activate recruited leukocytes.[7] 781
Bacterial products, particularly lipopolysaccharide and other cell wall components, are potent activators of leukocytes recruited into the tissue. Once the inflammatory response has been initiated, TNF-α, IL-1β, and other proinflammatory products of neutrophils, monocytes, mast cells, and epithelial cells amplify the inflammatory response.

The enteric nervous system has a key role in sensing and regulating inflammatory responses in the intestine. For example, *Clostridium difficile* toxin A activates a neural pathway that triggers mast cell degranulation and neutrophil influx into the tissue.[8,9] Blockade of this neural pathway is sufficient to abolish the profound inflammatory response induced by toxin A and many of the effects of toxin A on enterocyte secretion. Other pathogens and immune-mediated hypersensitivity reactions similarly stimulate inflammation by mechanisms that involve the enteric nervous system. Thus the epithelium interacts in a highly complex manner with the intestinal milieu, the enteric nervous system, and inflammatory cells to regulate the tissue response to injury and infection.

13.2.1.2 MACROPHAGES

Resident macrophages located in the lamina propria, submucosa, and intestinal lymphoid organs are among the first cells beyond the epithelium to respond to infection or injury. Macrophages are activated by bacterial products via pattern recognition receptors and begin to produce proinflammatory molecules important for recruiting and activating neutrophils and monocytes. Pattern recognition receptors recognize microbial products ranging from lipopolysaccharide to peptidoglycan and even CpG-containing bacterial DNA and signal the invasion by pathogens. Of the pattern recognition receptors, the lipopolysaccharide receptor complex is perhaps the best defined. Lipopolysaccharide activates macrophages via the CD14–Toll-like receptor complex to initiate transcription of the inflammatory cytokines TNF-α and IL-1β, which synergize with lipopolysaccharide to amplify the macrophage response.[10] Lipopolysaccharide, particularly in concert with inflammatory cytokines, stimulates macrophages to produce copious amounts of nitric oxide, which is microbicidal and vasoactive. Nitric oxide and other nitrogen radicals react with reactive oxygen intermediates (ROIs) to produce some of the most toxic molecules of the host defense system: the peroxynitrites.[11] IL-8 is produced as well to recruit neutrophils. As the response progresses, other inflammatory mediators, particularly the arachidonic acid–derived lipids, are produced. These lipids have potent vasoactive effects and are important stimuli of endothelial cells, neutrophils, and platelets.

13.2.2 Vascular Response During Inflammation

Four important changes occur in the intestinal vasculature during inflammation:

1. Alteration of blood flow
2. Increased vascular permeability
3. Increased adhesiveness of endothelial cells, leukocytes, and platelets
4. Exposure of the basement membrane and activation of the complement, contact, and coagulation cascades

A wide range of mediators alters blood flow during intestinal tract inflammation, from gasses such as nitric oxide (a major vasodilator of the intestinal vasculature) to lipids (prostaglandins, leukotrienes, thromboxanes, and platelet-activating factor), cytokines, bradykinin, histamine, and others. The major sources for these mediators include activated leukocytes, endothelial cells, epithelial cells, and fibroblasts. The primary determinant of blood flow early in inflammation is vascular caliber, which initially decreases in arterioles, but then quickly changes to vasodilation coincident with opening of new capillary beds, increasing net blood flow. The increase in blood flow is short lived, for the viscosity of the blood increases because of fluid loss and tissue edema through leaky capillaries. Leukocyte margination, platelet adhesion to endothelial cells and exposed matrix, and areas of coagulation protein accumulation further decrease local circulation.

Inflammatory mediator actions on the endothelial cells initially increase vascular permeability. Histamine, leukotrienes, platelet-activating factor, prostaglandins, bradykinin, and other mediators stimulate endothelial cell contraction, and interendothelial gaps form.[12,13] This stage of increased vascular permeability is readily reversible. Concurrently, mediators such as the cytokines TNF-α and IL-1β induce a structural reorganization of the interendothelial junctions, resulting in frank discontinuities in the endothelial monolayer.[14] Cytokines also stimulate endothelial cells to express adhesion molecules that support adhesion of leukocytes and platelets,[15]

leading to the next and perhaps most devastating event. Leukocytes (primarily neutrophils) and platelets adhere to exposed basement membranes and activated endothelial cells. Adherent neutrophils and platelets then are exposed to the mediators of inflammation present in the surrounding milieu, which activates the cells to release oxidants and proteases (particularly elastase) that injure the endothelium and have the potential to cause irreparable harm to the microvasculature.[16–18] Marginated neutrophils begin to transmigrate between endothelial 781
cells (as described in later sections), and if their numbers are large enough, they disrupt the integrity of the 782
interendothelial junctions, worsening the vascular leakage.[17]

Conceptually, these stages of enhanced vascular permeability can be thought of as a mechanism to allow plasma proteins to enter the tissues and to potentiate the critical influx of leukocytes into tissues. However, if not regulated precisely, alterations in hydrostatic and oncotic forces and irreversible damage to the vascular bed may have devastating consequences. Moreover, inappropriate activation of plasma protein cascades and leukocytes by activated endothelium and exposed matrix proteins can contribute to systemic inflammation (systemic inflammatory response syndrome; see Chapter 13.7 for more information) characterized by hypotension, generalized vascular leak syndrome, and multiorgan dysfunction, which may be fatal. Phosphodiesterase inhibitors reduce endothelial permeability in ischemia-reperfusion injury and other models of inflammation-induced vascular leakage[19,20] by increasing endothelial tight junction integrity and thus may be a viable therapeutic strategy to prevent or reduce the permeability alterations associated with inflammation.

13.2.3 Cellular Effectors of Inflammation

13.2.3.1 ENDOTHELIAL CELLS

Endothelial cells respond to products of activated epithelial cells and macrophages in the intestinal tissue to recruit cells and humoral mediators of inflammation into the tissue. Activated endothelial cells display a range of molecules critical for neutrophil and platelet adhesion. Intercellular permeability increases to expose basement membrane proteins that trigger humoral defense systems (complement, coagulation, and contact system cascades) and to provide access for these macromolecules to the tissue. Endothelial cells are an important source of inflammatory mediators that amplify the response and vasoactive substances (particularly nitric oxide) that alter blood flow.

13.2.3.2 NEUTROPHILS

13.2.3.2.1 Recruitment

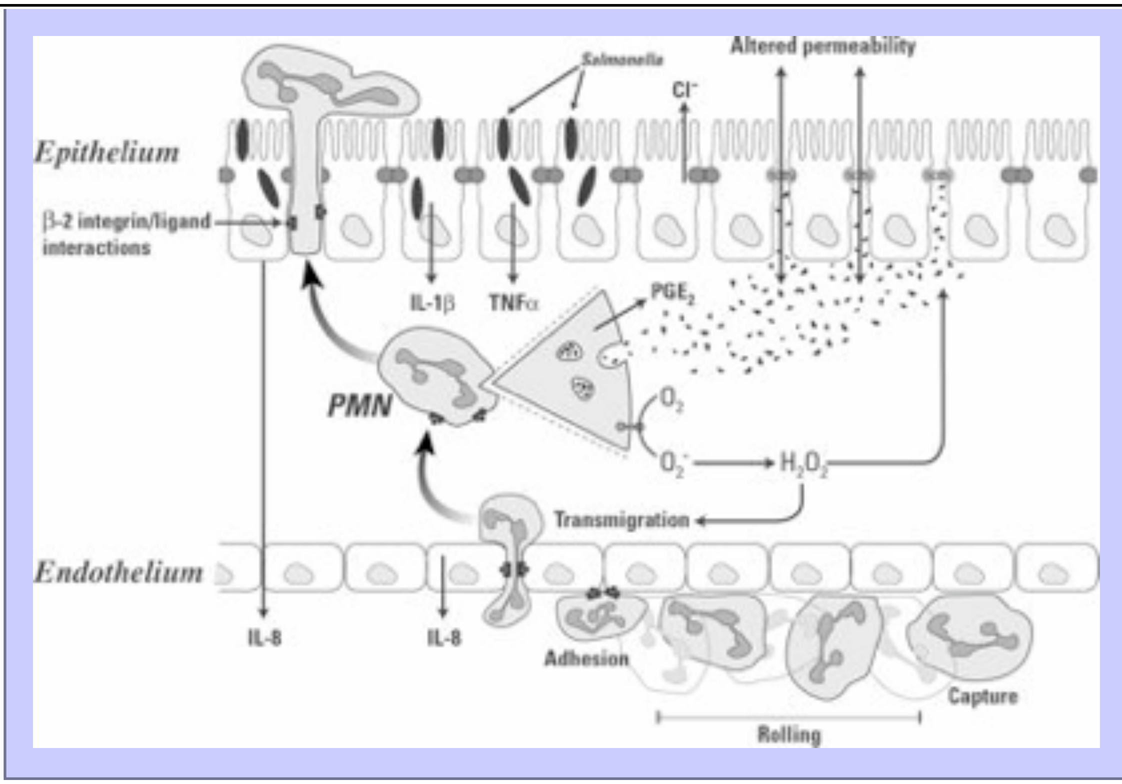
Infection or injury to the gastrointestinal mucosa causes an influx of leukocytes from the blood that lay the foundation of the inflammatory response. Neutrophils, being the first to arrive during inflammation, have a dominant role in the acute response. Within minutes, neutrophils are recruited into the tissue where they are activated to release products that not only are proinflammatory and lethal to pathogens but also may damage host cells and tissues. Not surprisingly, much attention has been paid to the role of neutrophils in the pathophysiology of many inflammatory conditions.[21] Neutrophil depletion is protective in many models of gastrointestinal inflammatory disease. Of interest to clinicians, blockade of neutrophil migration into inflamed tissues prevents many of the pathophysiologic events associated with infectious enteritis, ischemia-reperfusion injury, and other gastrointestinal diseases.[16,22–26]

Neutrophil transendothelial migration is a multistep process that is temporally and spatially regulated and has a degree of cell type specificity (Figure 13.2-1). The predominant sites of neutrophil transendothelial migration are in the postcapillary venules and, in some tissues, the capillaries. Endothelial cells in these vessels respond to cytokines and other soluble signals by expressing molecules that promote neutrophil adhesion and transmigration, including selectins and counterreceptors for integrins. As neutrophils flow through these vessels, they are first tethered to activated endothelium. Tethering is mediated by selectin molecules expressed on neutrophils (L-selectin) and on activated endothelial cells (P- and E-selectins) that bind to P-selectin glycoprotein ligand-1 (PSGL-1), E-selectin ligand-1 (ESL-1), and other mucin counterreceptors.[27,28] Tethering functions to increase the exposure of the neutrophil to activating chemokines presented on the surface of the endothelial cells.

Stimulation of neutrophils by IL-8 and other chemokines activates the second step of transendothelial migration. Chemokine binding to their receptors on the neutrophil generates signals that activate the binding of integrin adhesion receptors to their ligands, called intracellular adhesion molecules or vascular cell adhesion molecules expressed on endothelial cells in inflamed mucosa. Integrin ligation to cellular adhesion molecules arrests the tethered neutrophils, resulting in firm adhesion to the endothelium. Of the integrins expressed on neutrophils, the β_2 integrins have a particularly important role in transendothelial migration. Calves and human beings with a disorder known as leukocyte adhesion deficiency illustrate the requirement for β_2 integrin–mediated adhesion in neutrophil function. Leukocyte adhesion deficiency results from an autosomal recessive trait causing the lack of the β_2 integrin expression. The neutrophils from these individuals cannot migrate into most tissues and do not function normally, resulting in poor tissue healing and profound susceptibility to infection, especially at epithelial barriers.[29,30] Other integrins also have a role in transendothelial migration. β_1 Integrins mediate transendothelial migration in some cells and seem to be particularly important for mediating emigration of monocytes into many tissues.[31]

Following this firm adhesion step, neutrophils migrate through the endothelium along a chemotactic
gradient of IL-8 and other chemoattractants such as leukotriene B_4.[3,17,32] Neutrophils migrate across the 782
endothelial monolayer at intercellular junctions via a mechanism involving a series of integrin-ligand 783
interactions mediated by β_2 and β_1 integrins and other adhesion molecules[28] that is generally capable of maintaining the integrity of the endothelial barrier.[33] However, massive flux of neutrophils through the endothelium alters endothelial tight junctions and injures the basement membrane, resulting in increased endothelial permeability to molecules as large as plasma proteins and even endothelial cell detachment from the basement membrane.[17,18] Nonintegrin molecules such as platelet/endothelial cell adhesion molecules (PECAMs) also are involved in transendothelial migration of neutrophils.[28] Homotypic binding of PECAMs on adjacent endothelial cells form part of the intercellular junction. Neutrophils express an
integrin of the β_3 family that can bind PECAM, and via sequential binding of β_3 integrins to PECAM, the 783
neutrophil can "unzip" the intercellular junction and migrate through, closing it behind itself. 784

Figure 13.2-1 Depiction of neutrophil responses during intestinal inflammation in response to salmonella infection. Salmonellae infect epithelial cells, stimulating the production of chemokines (interleukin-8 [IL-8]), cytokines (IL-1β and tumor necrosis factor-α [TNF-α]), and other proinflammatory mediators. Endothelial cells stimulated by inflammatory mediators produce chemoattractants (such as IL-8) and display adhesion molecules that promote neutrophil emigration. The three steps of neutrophil (polymorphonuclear [PMN]) emigration— capture/rolling (mediated by selectins), adhesion (mediated by β_2 integrins), and transendothelial migration (mediated by integrins and platelet/endothelial cellular adhesion molecule [PECAM])— occur on activated endothelium. Chemoattractant molecules, such as IL-8 trigger neutrophil emigration. In inflamed tissues, cytokines (IL-1β and TNF-α) and a variety of other proinflammatory mediators stimulate the neutrophil oxidase complex to produce reactive oxygen intermediates (ROIs; O_2^- and H_2O_2 and their derivatives). Activated neutrophils degranulate to release proteases and other hydrolases, cationic peptides (defensins), myeloperoxidase, and other products into the tissue. Activated neutrophils synthesize a variety of inflammatory mediators, including prostaglandins (PGE_2) that modulate the inflammatory response. The products of activated neutrophils (ROIs, proteases, and mediators) stimulate epithelial secretion and alter tight junction permeability, promoting diarrhea. Neutrophils eventually migrate across the infected epithelium by a mechanism that involves integrins, disrupting tight junction integrity and increasing permeability to bacterial products, thus exacerbating the inflammatory response.



13.2.3.2.2

Activation

A key feature of neutrophils and other leukocytes is the requirement for integrin-mediated adhesion to extracellular matrix proteins (ECMs) or other cells to achieve an optimal effector phenotype.[34] Critical components of the ECMs in inflamed tissues include fibronectin, fibrinogen, and vitronectin, deposited in tissues as a result of plasma leakage and by synthesis of new proteins by stromal cells and resident macrophages in response to inflammatory mediator activation. The changing composition of the matrix proteins deposited in tissues during inflammation serves as a clue as to the nature of the tissue environment for recruited inflammatory cells as they become activated. Individual gene expression studies have demonstrated that adhesion to matrix proteins induces the expression of cytokines and chemokines and their receptors, arachidonic acid–derived lipid mediator synthases, metalloproteinases, growth factors, transcription factors, and other genes that influence the differentiation and activation of inflammatory cells.[35] ROI production, phagocytosis, degranulation, and other effector functions stimulated by inflammatory mediators and bacterial products are optimal only when neutrophils adhere to the ECMs.[34] Adhesion to distinct ECM proteins selectively activates signaling pathways and gene expression of neutrophils, monocytes, and other leukocytes with differing abilities to promote certain functions such that the composition of ECMs in many ways controls the development of the ultimate effector phenotype. Thus integrin-mediated adhesion provides a mechanism by which neutrophils and other leukocytes can sense the complex tissue environment and respond appropriately.

Of the activators of neutrophils at sites of inflammation, complement (C3-opsonized particles), cytokines (TNF-α and IL-1β), platelet-activating factor, immune complexes, and bacterial products are among the most potent stimuli. Other mediators produced during inflammation may modify neutrophil activity, particularly formylated bacterial peptides, chemokines, complement fragments (C5a), leukotriene B_4, and

prostaglandins. Activated neutrophils are highly phagocytic; produce large amounts of ROIs; degranulate to release myeloperoxidase, cationic antimicrobial peptides (defensins), serine proteases (mainly elastase), and metalloproteinases; and secrete inflammatory mediators (TNF-α, IL-1β, prostaglandins, leukotrienes, and others) (see Figure 13.2-1).

13.2.3.3 MAST CELLS

Mast cells strategically reside in mucosal tissues, including the submucosa and lamina propria of the gastrointestinal tract, and constitute a crucial first line of defense at epithelial barriers. However, they are also important effector cells of the pathophysiology of inflammatory gastrointestinal diseases.[36] Experimental depletion of mast cells, genetic deficiency in the development of mast cells, or pharmacologic stabilization of mast cells to prevent degranulation have a protective effect in a variety of models of gastrointestinal inflammatory disease, including dextran- or trinitrobenzenesulfonic acid–induced colitis,[37,38] ischemia-reperfusion injury,[39,40] and immediate hypersensitivity responses.[41]

Mast cells are activated by a wide variety of microbial products and host-derived mediators.[42] Among the activators of mast cells the so-called anaphylatoxins (complement fragments C3a, C5a, and C4a), are potent stimuli causing release of mediators of inflammation. In addition, mast cells are the primary effector cells of immunoglobulin E–mediated anaphylaxis (type I hypersensitivity reactions) by virtue of their high affinity receptors for immunoglobulin E. Cross-linking of receptor-bound immunoglobulin E on mast cell surface by antigens (i.e., food antigens) causes rapid degranulation, resulting in the explosive release of granule contents.[43] Neural pathways in the intestine also regulate mast cells. Mast cells respond to enteric pathogen invasion via neural reflexes that stimulate the release of inflammatory mediators.

Activated mast cells release preformed histamine, 5-hydroxytryptamine, proteases, heparin, and cytokines from granules. Activation also stimulates de novo synthesis of a range of inflammatory mediators, including prostaglandins, platelet-activating factor, and leukotrienes. Transcription of a number of peptide mediators, such as the cytokines TNF-α and IL-1β among many others, also increases on stimulation of mast cells. Mast cell products have profound effects on the vasculature, increasing endothelial permeability and causing vasodilation.[44] Moreover, mast cell–derived mediators greatly enhance epithelial secretion by a mechanism that activates neural pathways of epithelial secretion and directly stimulates epithelial cells.[43] Mast cell products significantly alter intestinal motility, generally increasing transit and expulsion of intestinal contents. Mast cell–derived leukotrienes and TNF-α also have a crucial role in host defense against bacterial pathogens, acting to recruit and activate neutrophils.[45,46]

Mast cells have a newly identified role in host defense and inflammatory responses to bacterial pathogens, which in part is caused by the release of proinflammatory mediators during bacterial infection, which is critical for recruiting and activating other innate host defense cells such as neutrophils. However, mast cells are also phagocytic, have microbicidal properties, and can act as antigen-presenting cells to the adaptive immune system.[47] Although accumulating evidence was establishing the role of mast cells in innate immunity, a seminal study that unconditionally identified the importance of mast cells in host defense demonstrated that mast cell–deficient W/W^v mice have impaired responses to gram-negative bacterial peritonitis, resulting in a significant increase in mortality. The role for mast cells in host protective responses appears to be as a sensor of bacterial invasion. Unlike immunoglobulin E–mediated responses, bacterial products seem to elicit a highly regulated and selective response from mast cells.

784

785

13.2.4 Humoral Mediators of Inflammation

13.2.4.1 COMPLEMENT

The complement cascade is a fundamental part of the inflammatory response. Activation of the complement cascade by immune complexes (classical pathway) or by bacteria or bacterial products, polysaccharides, viruses, fungi, or host cells (alternative pathway) results in the deposition of complement proteins on the activating surface and the release of soluble proteolytic fragments of several complement components. In particular, activation of either pathway results in the deposition of various fragments of the complement protein C3, which are potent activators of neutrophils and monocytes.[48] Opsonization of particles with C3 fragments constitutes a major mechanism of target recognition and phagocyte activation.[49] During the activation of the complement cascade culminating in deposition of C3, soluble fragments of C3 (C3a), C5 (C5a), and C4 (C4a) are liberated. These fragments, termed *anaphylatoxins,* have potent effects on tissues and cells during inflammation. Perhaps most notably, anaphylatoxins are chemotactic for neutrophils (particularly C5a), activate neutrophil and mast cell degranulation, and stimulate ROI release from neutrophils.[48] The termination of the complement cascade results in the formation of a membrane attack complex in membranes at the site of complement activation, and if this occurs on host cells such as endothelium, it may cause irreversible cell injury. Although the primary source of complement is plasma, epithelial cells of the gastrointestinal tract also produce C3, suggesting that local production and activation of the complement cascade during inflammation occurs in intestinal tissues.

Clearly, if the regulatory mechanisms of the complement cascade fail, then the inflammatory response may be inappropriate and tissue injury can occur. The role of complement in gastrointestinal inflammation has been most studied extensively in models of ischemia-reperfusion injury. Activation of the complement cascades has a major role in altered endothelial and epithelial permeability in these models. Several lines of evidence support the importance of complement in intestinal injury. Mice deficient in C3 or C4 are protected against ischemia-reperfusion injury.[50] Moreover, administration of monoclonal antibodies against C5 reduced local and remote injury and inflammation during intestinal reperfusion injury in a rat model.[51] Administration of a soluble form of complement receptor 1, a regulatory protein that halts the complement cascade by dissociating C3 and C5 on host cell membranes, reduced mucosal permeability, neutrophil influx, and leukotriene B_4 production during ischemia-reperfusion injury in rats and mice.[50,52] Although neutrophils and mast cells mediate many of the pathophysiologic effects of the complement cascade, the membrane attack complex may have a primary role in altered vascular permeability during ischemia-reperfusion injury.[53]

13.2.4.2 CONTACT SYSTEM

Four components initiate the contact system of coagulation: Hageman factor (HF), prekallikrein, factor XI, and high-molecular-weight kininogen. HF is a large plasma glycoprotein that binds avidly to negatively charged surfaces.[54] Bacterial cell walls, vascular basement membranes, heparin, glycosaminoglycans, and other negatively charged surfaces in the intestine capture HF and the other three important initiators of the contact system in a large multimolecular complex. Of the surfaces that bind HF, the extracellular matrix is a potent activator of the contact system. Once bound, HF is converted to HF-α, which cleaves prekallikrein to kallikrein and factor XI to factor XIa. The ultimate result is further cleavage of HF by kallikrein and triggering of the contact system cascade, activation of intrinsic coagulation by factor XIa, activation of the alternative

pathway by HF, and proteolytic cleavage of high-molecular-weight kininogen by kallikrein, releasing biologically active kinins.

The products of the contact system, particularly bradykinin, have several important biologic properties that drive many of the vascular and leukocytic responses during inflammation.[54] Bradykinin induces endothelial cell contracture and intracellular tight junction alterations that increase vascular permeability to fluid and macromolecules. Bradykinin also affects vascular smooth muscle contracture, resulting in vasoconstriction or vasodilation depending on the location. Bradykinin also increases intestinal motility, enhances chloride secretion by the intestinal mucosa, and intensifies gastrointestinal pain. In neutrophils, kinins stimulate the release of many inflammatory mediators, including cytokines, prostaglandins, leukotrienes, and ROIs.[55] Kallikrein cleaves C5 to release C5a, a potent chemotactic factor for neutrophils, and thus has a role in recruiting and activating inflammatory leukocytes.

The plasma kallikrein-bradykinin system is activated in a variety of acute and chronic inflammatory diseases 785
of the gastrointestinal tract.[56,57] Recent evidence has demonstrated that blockade of the pathophysiologic 786
effects of bradykinin has clinical applications. Oral or intravenous administration of the bradykinin receptor antagonist icatibant reduces the clinical signs, onset of diarrhea, and many of the histopathologic changes in experimental models of colitis in mice.[58] Inhibition of kallikrein by oral administration of P8720 attenuated the intestinal inflammation, clinical score, and systemic manifestations in a model of chronic granulomatous enterocolitis.[57] Thus the contact system is a viable therapeutic target for inflammatory diseases of the intestine.

13.2.5 Tissue Injury During Inflammation

Changes in blood flow to the mucosa and other regions of the intestine that reduce perfusion of the tissues can potentiate the initial damage caused by infection or injury. For example, reperfusion of ischemic tissues is associated with platelet and neutrophil clumping in the small vessels of the mucosa, which can impede blood flow.[59] Platelets are activated and adhere to exposed basement membrane and activated endothelial cells and provide a surface for leukocyte adhesion. The accumulation of platelets and leukocytes can reduce vessel diameter and blood flow significantly while potentiating local coagulation and thrombus formation.

Soluble mediators released by activated leukocytes and endothelial cells also affect blood flow. Histamine and the vasoactive lipids derived from arachidonic acid (leukotrienes, prostaglandins, thromboxane, prostacycline, and platelet-activating factor) have a prominent role in regulating local perfusion during inflammation and also may have systemic effects on blood flow. Procoagulant mediators released by inflammatory cells in response to the inflammatory process (i.e., tissue factor produced by macrophages or endothelial cells), exposed basement membrane proteins, and bacterial components can trigger the contact system and the coagulation and complement cascades, the products of which affect blood flow. Nitric oxide, whether produced by endothelial cells or leukocytes (macrophages), is a potent regulator of blood flow and has a significant role in the control of perfusion during inflammation.[60] Many of the mediators that affect perfusion also affect endothelial permeability, altering osmotic and hydrostatic balance and tissue edema. In extreme cases, local and systemic coagulopathies initiated by vascular injury and absorption of microbial products and inflammatory mediators induce a hypercoagulable state, leading to microthrombus formation, which can reduce blood flow, or macrothrombus formation, which causes tissue infarction.

The cellular mediators of inflammation have the potential to inflict severe injury to intestinal tissues. Neutrophils have an important role in the pathophysiology of many intestinal diseases, including ischemia-reperfusion injury,

[16,22] infectious enterocolitis,[23–25] nonsteroidal antiinflammatory drug–induced mucosal ulceration,[26] and others. Depletion of neutrophils, blockade of their emigration into tissues, or inhibition of neutrophil activation reduce the severity of these and other inflammatory diseases.[61] Thus many antiinflammatory therapies are emerging that specifically target neutrophil adhesion, migration, and activation.

Migration of neutrophils through endothelium during emigration into inflamed tissues is remarkable in that the permeability of the endothelial monolayer is preserved under most circumstances. However, a limit exists above which neutrophil migration alters the permeability characteristics of the endothelium. The effect is in part physical in that mere movement of large numbers of neutrophils through the endothelium is sufficient to disrupt the tight junctions mechanically and is caused in part by toxic products of neutrophils that damage endothelial cells and basement membranes.[59,62] Serine proteases (particularly elastase) and metalloproteinases released by degranulating neutrophils destroy tissue matrix proteins and cell-surface proteins that make up endothelial intercellular junctions. These degradative enzymes are particularly damaging to basement membranes and the cellular barriers of the endothelium, thus contributing to vascular permeability (and local tissue edema) and thrombosis. The permeability may be affected to the extent that not only water but macromolecules (albumin, matrix proteins, complement, etc.) leak into the interstitium. Blockade of neutrophil adhesion to endothelium with anti–β_2 integrin antibodies has a sparing effect on the microvasculature in experimental intestinal ischemia-reperfusion injury, reducing the alterations in vascular permeability and histopathologic evidence of microvascular damage.[59]

Similar to the endothelium of inflamed tissues, massive neutrophil transmigration occurs across the epithelium in response to infection or injury. Neutrophil transepithelial migration increases epithelial permeability by disrupting tight junctions.[62] Like the endothelium, neutrophils disrupt the epithelial barrier mechanically as they migrate through (see Figure 13.2-1). Proteases, particularly elastase, degrade basement membrane components and tight junction proteins. Products of activated neutrophils (TNF-α and interferon-γ) increase tight junction permeability by direct effects on the enterocytes. Prostaglandins released by activated neutrophils stimulate epithelial secretion, thus contributing to diarrhea. Subepithelial accumulation of neutrophils can lead to deadhesion of the epithelial cells from the basement membrane and mild to severe ulceration. The physiologic 786
results of the effects of neutrophils and their products on the epithelial barrier include protein-losing enteropathy 787
and absorption of bacterial cell wall constituents, which potentiates the local and systemic inflammatory responses.

Neutrophils in inflamed tissues stimulated by potent host-derived activators (such as IL-1β and TNF-α) and bacterial products (lipopolysaccharide) release copious amounts of ROIs (see Figure 13.2-1). Although these oxygen and oxyhalide radicals are important for killing pathogens, they are also potentially toxic to epithelial and endothelial cells and matrix proteins. Reactive nitrogen intermediates produced primarily by macrophages during inflammation combine with ROIs to form peroxy nitrites, which are particularly toxic.[11] In addition to injury to mucosal tissues, ROIs also have an as yet ill-defined role in recruiting and activating neutrophils, thereby potentiating the inflammatory response.[63] In support of the role of ROIs in inflammatory diseases of the gastrointestinal tract, administration of inhibitors of ROI production or pharmacologic ROI scavengers can be protective in many models of reperfusion injury or enterocolitis. Many therapies are aimed at inhibiting neutrophil activation and effector functions in tissues have been evaluated for use in intestinal diseases. Phosphodiesterase inhibitors, by causing cyclic adenosine monophosphate accumulation in neutrophils, are antiinflammatory by virtue of their ability to suppress neutrophil activation and ROI production. New phosphodiesterase inhibitors selective for the predominant neutrophil isoform of phosphodiesterase hold promise for use in many inflammatory diseases.

Subepithelial mast cells also have an important role in altering epithelial permeability in inflamed intestine. During the intestinal hypersensitivity response, subepithelial mast cell release of mast cell protease II by degranulation increases epithelial permeability via an effect on tight junctions.[41,64,65] This alteration in tight junction permeability results in enhanced transepithelial flux of macromolecules, including proteins and bacterial products. Cytokines released by mast cells and phagocytes also regulate tight junction permeability. Interleukin-4, a product of mast cells and macrophages, increases epithelial permeability.[66] Moreover, TNF-α and interferon-γ, products of many inflammatory cells, synergistically increase tight junction permeability.[67]

13.3

13.3—Pathophysiology of Diarrhea

Rebecca S. McConnico

Acute equine colitis causes rapid, severe debilitation and death in horses (more than 90% of untreated horses die or require euthanasia).[1] Since 1919, several reports have described a number of different acute diarrheal conditions in the horse that appear to share a common characteristic clinical presentation.[2–10] Diarrhea associated with acute equine colitis occurs sporadically, is highly fatal, and is characterized by intraluminal sequestration of fluid, moderate to severe colic (abdominal pain), and profuse watery diarrhea with resultant endotoxemia, leukopenia, and hypovolemia.[7,10,11] The condition can affect adult horses of all ages but usually occurs in horses between 2 and 10 years of age. Disease onset is sudden with a rapid progression and often is preceded by a stressful event. A definitive diagnosis is made in only about 20% to 30% of cases.[7,11] Most ante- and postmortem diagnostic tests remain speculative.

Treatment of the condition in horses is costly because of the massive fluid therapy required. Currently, no curative treatment is available for acute colitis in horses, human beings, or other mammals. Treatment regimens provide rehydration, electrolyte and plasma protein replacement, mitigation of the effects of circulating endotoxin, and antimicrobial therapy when indicated. Attempts during the past 40 years to develop appropriate treatments (i.e., vaccines or pharmacologic agents) have been hampered by the unavailability of acceptable equine models and have been unsuccessful because of the complex pathophysiology of the intestinal epithelium.

Although the mechanisms responsible for the fluid losses are not known, inflammatory cells may play an integral role because this condition is characterized by large numbers of granulocytes infiltrating the large intestinal mucosa.[12–16] Equine cecal and colonic tissues collected during the acute stages of experimentally induced acute equine colitis (equine ehrlichial colitis, lincomycin with and without *Clostridium* spp. inoculation, nonsteroidal antiinflammatory drug administration) reveal the presence of numerous neutrophils and eosinophils in the lamina propria and submucosa.[12,15,17,18] Granulocyte-derived reactive oxygen intermediates are crucial to antimicrobial defenses in the gut and stimulate chloride and water secretion by interactions with enterocytes.[19,20] Normal equine intestinal tissue is unique compared with that in most other mammalian species for a preponderance of eosinophils located in the intestinal mucosa and submucosa.[6,21] Production of reactive oxygen intermediates by stimulated phagocytic granulocytes following mucosal barrier disruption may be responsible for the massive fluid secretory response that occurs during the early stages of acute equine colitis.

Colitis refers to inflammation and mucosal injury of the colon and cecum (typhlocolitis) that may occur in response to a number of causes.[22,23] The cause of the colonic injury may be well-defined such as in naturally occurring infectious or experimentally induced colitis. However, many cases of human and animal diarrhea have a speculative or unknown diagnosis or no diagnosis.[11,24,25] Irrespective of the underlying or initiating cause of colonic injury, the colon apparently has a limited repertoire of responses to damage because most forms of colitis demonstrate similarities in histopathologic appearance and clinical presentation. Various degrees of mucosal erosion and ulceration, submucosal/mucosal edema, goblet cell depletion, and presence of an inflammatory cellular infiltrate within the mucosa and submucosa are common to many types of human and animal colitis.[21,23–25] Characteristic clinical manifestations include intraluminal fluid sequestration, abdominal discomfort, hypovolemia, and most often profuse, watery diarrhea.

13.3.1 Pathophysiology of Colitis

Large bowel diarrhea results from abnormal fluid and ion transport by cecal and colonic mucosa. Loss of fluid by the large intestine can result from malabsorptive or hypersecretory processes and is often a combination of the two.[26] Colonic secretory processes are a function of the crypt epithelium, whereas absorptive processes are limited to surface epithelial cells.[27] Under normal baseline conditions, an underlying secretion by crypt epithelium is masked by a greater rate of surface epithelial cell absorption. Abnormal forces influencing the rates 789
of secretion and absorption can result in massive, uncontrolled secretion and malabsorption by large intestinal 790
mucosal epithelial cells, leading to rapid dehydration and death.[26,27]

Two intracellular processes control colonic secretion: the cyclic nucleotide (cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate [cGMP]) and the calcium system.[28,29] Agents may activate adenyl cyclase (vasoactive intestinal peptide, prostaglandin E_2 [PGE_2]) or guanyl cyclase (bacterial enterotoxins) and induce increases in cAMP or cGMP, respectively. This reaction causes phosphorylation of specific protein kinases that induce the actual apical and basolateral membrane transport events. Increases in intracellular free

calcium may arise from cyclic nucleotide–dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane.[26,27] Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases.

At least four central systems control intestinal secretion: (1) the hormonal system, (2) the enteric nervous system, (3) bacterial enterotoxins, and (4) the immune system.[29,30] Hormonal control of colonic electrolyte transport is exerted primarily through the renin-angiotensin-aldosterone axis.[31,32] The enteric nervous system controls transport through three separate components: (1) extrinsic nerves of the parasympathetic and sympathetic pathways; (2) intrinsic ganglia and nerves, secreting a variety of neurotransmitters including peptides; and (3) neuroendocrine cells (intraepithelial lymphocytes) that reside in the epithelium and release messengers onto the epithelial cells in a paracrine manner.[26,29–32] Many bacterial enterotoxins can induce intestinal secretion by cAMP or cGMP signal transduction.[33] Bacterial enterotoxins can stimulate enteric neurons, providing evidence for interaction between two controlling systems.[34]

Preformed inflammatory mediators such as histamine, serotonin, or adenosine and newly synthesized mediators such as prostaglandins, leukotrienes, platelet-activating factor, various cytokines, the inducible form of nitric oxide, and reactive oxygen metabolites can initiate intestinal secretion by directly stimulating the enterocyte and by acting on enteric nerves indirectly to induce neurotransmitter-mediator intestinal secretion.[30] For instance, when added to the T84 colonic cell line, the known mast cell mediators histamine, adenosine, and PGD_2 induce chloride secretion.[35–37] Prostaglandins of the E and F series can cause an increase in chloride secretion in intact tissue and isolated colonic cells.[38–40] Leukotrienes, platelet-activating factor, and a number of cytokines have been shown to have no effect on T84 cell secretion but have a significant effect on electrolyte transport in intact tissue, suggesting that intermediate cell types may be involved in these secretory responses.[41–43]

The epithelial cell chloride secretory response occurs via prostaglandin- and adenosine-mediated increases in cellular cAMP, whereas histamine acts by H_1 receptor induction of phosphatidylinositol turnover, production of inositol triphosphate, and mobilization of intracellular calcium stores.[30,33] Lipoxygenase products (leukotrienes) are capable of activating a colonic secretory response and do not appear to involve the cyclic nucleotides or calcium ions.[41] Phagocyte-derived reactive oxygen mediators (ROMs) can induce colonic electrolyte secretion in vitro, suggesting that oxidants may contribute directly to the diarrhea associated with colitis.[44–48] Reactive oxygen species initiate the secretory response by increasing cellular cAMP or stimulating mesenchymal release of PGE_2 or prostacyclin, which in turn stimulates the epithelial cell or enteric neuron, respectively.[44–49] Sodium nitroprusside, an exogenous source of nitric oxide, stimulated an increase in chloride secretion in rat colon that was mediated by cyclooxygenase products and enteric neurons.[50] Table 13.3-1 summarizes inflammatory mediator– induced epithelial cell chloride secretion.

13.3.2 Role of Inflammatory Cells

Acute colitis rarely develops by a simple cause or effect phenomenon but is influenced by many extrinsic and intrinsic host and microorganism factors. Inflammatory mediators released from mast cells and monocytic or granulocytic phagocytes cause intestinal chloride and water secretion and inhibit neutral sodium and chloride absorption.[29,30,67] Inflammatory cells, particularly the phagocytic granulocytes, play an important role in mucosal pathophysiology in cases of colitis.[20,68] Large numbers of these cells are observed on histopathologic examination of tissues from human and animal cases of colitis. Products of cell activation stimulate direct and

indirect secretory responses in intestinal cells and tissues.[28–30,45–49] Products of phagocyte secretion may amplify the inflammatory signal or have effects on other target cells in intestine such as enterocytes and smooth muscle cells (Table 13.3-2).

13.3.3 Role of Phagocyte-Derived Reactive Oxygen Metabolites

The NADPH-oxidase system of phagocytes (neutrophils, eosinophils, monocytes/macrophages) is a potent inducer of superoxide radicals used as a host defense mechanism to kill invading microorganisms.[20,69] During inappropriate stimulation such as inflammation, trauma, or ischemia followed by reperfusion, increased levels of toxic oxygen species are produced, causing damage to host tissues. Engagement of any of several receptor and 790
nonreceptor types including phagocytosis mediators, chemotactic agents, various cytokines, and microbial 791
products can stimulate phagocytes.[20] Resident phagocytes or those recruited to colonic mucosa early in the disease process are considered to augment mechanisms causing fluid and electrolyte secretory processes, a so-called amplification process.[70,71]

TABLE 13.3-1 Inflammatory Mediators That Stimulate Epithelial Cell Chloride Secretion

MEDIATOR	ACTION	REFERENCE
Prostaglandin E_2	Increases Cl secretion.	51
	Decreases neutral NaCl absorption.	
Vasoactive intestinal peptide	Increases cAMP-mediated NaCl secretion.	52
	Activates cholinergic nerves.	53
Endotoxin	Increases Na absorption.	54
	Increases cell membrane permeability.	
Serotonin	Increases fluid and electrolyte secretion.	55
Interferon-γ	Decreases tight junctions and causes increase in cell membrane permeability.	56
Interleukin-1α and interleukin-1β	Increase prostaglandins E_2 and $F_{1\alpha}$ and thromboxane B_2.	57
Histamine (H_1)	Increases Cl secretion via Ca-mediated pathways.	[58] and [59]
Bradykinin	Increases Cl secretion through prostaglandin-mediated pathways.	60 and 61
Reactive oxygen mediators	Increase Cl secretion.	44 and 62
Thromboxanes	Increase Cl secretion.	63
	Decrease neutral NaCl absorption.	
Lipoxygenase products	Increase Cl secretion via prostaglandin-mediated pathways.	64
Platelet-activating factor	Increases Isc (Cl secretion).	65
Adenosine	Increases Cl secretion.	66

cAMP, Cyclic adenosine monophosphate.

Activation of the respiratory burst results in the production and release of large amounts of superoxide anion (O_2^-) and H_2O_2.[69,72] In addition to these ROMs, activated phagocytes secrete peroxidase enzyme (myeloperoxidase from neutrophils and eosinophil peroxidase from eosinophils) into the extracellular space. The peroxidases catalyze the oxidation of Cl^- by H_2O_2 to yield HOCl, the active ingredient in household bleach products. The peroxidase-H_2O_2-halide system is the most cytotoxic system of the phagocytes; HOCl is 100 to 1000 times more toxic than O_2^- or H_2O_2.[69] HOCl is a nonspecific oxidizing and chlorinating agent that reacts rapidly with a variety of biologic compounds including DNA, sulfhydryls, nucleotides, amino acids, and other nitrogen-containing compounds. HOCl reacts rapidly with primary amines (RNH_2) to produce the cytotoxic N-chloramines (RNHCl). The mechanisms by which HOCl and RNHCl damage cells and tissue remain speculative, but possibilities include direct sulfhydryl oxidation, hemoprotein inactivation, protein and amino acid

degradation, and inactivation of metabolic cofactors of DNA.[73] Peroxidase-derived oxidants have been shown to degrade hyaluronic acid and collagen.[74] In addition, luminal perfusion of specific ROMs increased mucosal permeability and serosal application caused increases in Cl^- secretion in vitro.[75]

TABLE 13.3-2 Phagocyte-Derived Inflammatory Mediators

ENZYME	MEDIATOR	MONOKINE	REACTIVE OXYGEN MEDIATOR
Protease	Platelet-activating factor	Interleukin-1	O_2^-
Kallikrein	Prostaglandin	Tumor necrosis factor	H_2O_2
Phospholipase	HPETE	Interferon-γ	OH^-
	Leukotriene		HOCl

HPETE, Hydroperoxyeicosatetraenoic acid.

791

792

Tissue myeloperoxidase activity, an index of tissue granulocyte infiltration, is used clinically and experimentally to assess degree of intestinal inflammation.[76,77] Myeloperoxidase activity is elevated in acute flare-ups of human inflammatory bowel disease and various animal models of acute colitis.[76–80]

The acute inflammatory response in these conditions is characterized predominantly by neutrophils, the predominant source of myeloperoxidase activity. However, this assay measures total hemoprotein peroxidase, which includes monocyte and eosinophil peroxidase in addition to neutrophils.[77] Moreover, levels of peroxidase activity in equine circulating eosinophils are greater than in circulating neutrophils,[81] and this may apply to resident tissue eosinophils as well.

Arachidonic acid metabolites are thought to play a role in intestinal inflammation in diarrheal disease.[30,45,82] Elevated levels of these intermediate metabolites have been demonstrated in natural disease and experimental models of colitis and appear to parallel increases in ROMs in inflamed intestine.[82] Addition of H_2O_2 or HOCl to rat colonic tissue in Ussing chambers has been shown to induce PGE_2 release and active Cl^- secretion.[47,48] Prostaglandins can stimulate increases in Cl^- secretion in intact intestinal tissue[45,46,48] and in isolated colonic T84 cells.[47,49] Interactions between ROMs and mesenchymal release of PGE_2/PGI_2 may be relevant to the mechanisms producing the diarrheic condition. Fibroblasts co-cultured or juxtaposed to colonic T84 cells greatly increased the Cl^- secretory response to H_2O_2 in vitro through the release of PGE_2.[49] In addition, equine colonic mucosa has an increased sensitivity to endogenously released prostaglandin by exhibiting a significant secretory response under in vitro conditions.[83]

13.3.4 Role of Endotoxin, Malnutrition, Immunodeficiency, and Intestinal Microflora

13.3.4.1 ENDOTOXIN

Endotoxin, the lipopolysaccharide component of the outer cell wall of gram-negative bacteria, is present in large quantities in the large intestine of healthy horses.[81,83] Endotoxins are released into the immediate

surroundings when gram-negative bacteria undergo rapid proliferation or die.[84,85] The intact bowel forms an effective barrier to the transport of significant amounts of these highly antigenic toxins, but the diseased gut absorbs these macromolecules in large amounts, causing the subsequent adverse systemic effects that are often life threatening.[86]

Disruption of the intestinal barrier (i.e., ischemia, trauma, inflammatory conditions) overwhelms the capacity of the liver to clear endotoxins, and systemic endotoxemia ensues. Endotoxins have been shown to be potent activators of the inflammatory process, stimulating the production and release of numerous cytokines by activated macrophages and other immunocytes.[87] In vitro studies suggest that endotoxin activates phagocytic granulocytes to secrete ROMs, increase release of lysozymes, and enhance the migratory response to chemotactic stimuli.[88] Prostacyclin and thromboxane A_2 mediate hemodynamic dysfunction, and lipoxygenase products may induce tissue ischemia.[89] The cytokine interleukin-1 causes a febrile response and initiates the acute phase response.[90] Tumor necrosis factor contributes to many of the abnormal physiologic responses, particularly hemostatic functions that potentiate coagulopathy.[91] Additional mediators include interleukin-6, platelet-activating factor, procoagulant mediators, and various other speculated substances.[84]

Endotoxins trigger mucosal immune cells and subsequent release of inflammatory mediators in cases of colitis. The first report of experimentally induced endotoxemia described clinical signs and hematologic findings that closely paralleled those reported for severe colitis in horses.[92] Studies in which endotoxin was administered intravenously in human beings and laboratory animals caused significant dose-related gastrointestinal changes, ranging from mild diarrhea to bloody, watery diarrhea.[93,94] In vitro studies on the effects of endotoxin on intestinal water and electrolyte transport in adult male rats showed a significant decrease in net colonic sodium absorption and increased colonic permeability.[55]

In animal models of protein energy deficiency, endotoxin-induced mortality increased compared with that of well-nourished control animals. Endotoxin depresses lymphocyte responses to specific mitogens.[95] Thus the adverse effects of malnutrition and endotoxin are mutually aggravating.

13.3.4.2 IMMUNODEFICIENCY

The importance of a normal immune system to the defense of the mucosal surface of the gastrointestinal tract is evident in the immunosuppressed state. Primary immunodeficiencies affecting the gastrointestinal tract are well documented.[96–98] Common agammaglobulinemia is the most frequently reported gastrointestinal disease and causes B cell deficiency–associated giardiasis.[99] Interestingly, selective immunoglobulin A (IgA) deficiency rarely results in intestinal disease because of a speculated increase in mucosal IgM response. However, combined IgA and IgM deficiencies with a higher incidence of intestinal disease occur. A selective deficiency of secretory IgA has been associated with intestinal candidiasis. Certain mucosal pathogens may enhance their pathogenicity by producing IgA proteases.[99] Defects in cell-mediated immunity are associated 792
most commonly with intractable diarrhea, and organisms frequently involved include *Salmonella* spp., 793
Escherichia coli, and *Shigella* spp.[100] Acquired immunodeficiency or immunosuppression in adults can result from infectious diseases (particularly viral), nutritional deficiencies, aging phenomenon, and drugs (corticosteroids, azathioprine, cyclophosphamide).

TABLE 13.3-3 Vitamin and Mineral Deficiency–Related Immunodeficiencies

DEFICIENCY	FUNCTION
Pyridoxine, folic acid, vitamin C, vitamin E	Impairs cell-mediated immunity and reduces antibody response.
Vitamin B_6	Decreases lymphocyte stimulation response to specific mitogens.
Zinc	Deficiency affects humoral and cell-mediated immunity.
Iron	Inhibits bacterial multiplication.
Copper	Depresses antibody response.

13.3.4.3 NUTRITIONAL DEFICIENCIES

Nutrition is a critical determinant of immunocompetence and risk of illness.[101,102] Impaired systemic and mucosal immunity contribute to an increased frequency and severity of intestinal infections observed in cases of undernourishment. Abnormalities occur in cell-mediated immunity, complement system, phagocytic function, mucosal secretory antibody response, and antibody affinity. Morbidity caused by diarrheal disease is increased particularly among individuals with stunted growth rate because of malnourishment.[102]

The critical role of several vitamins and minerals in immunocompetence has been substantiated in animals deprived of one dietary element and findings in human patients with single-nutrient deficiency. Tables 13.3-3 and 13.3-4 summarize nutritional-related immune system abnormalities.

TABLE 13.3-4 Vitamin and Mineral Excess–Related Immunodeficiencies

EXCESSES	FUNCTION
Vitamin A	Increases the immune response.
β-Carotene	Increases the number of $CD4^+$ cells.
Vitamin E and selenium	Enhance immunocompetence and increase resistance to microorganisms.
Zinc	Depresses neutrophil function and lymphocyte responses.
Iron	Needed by neutrophils and lymphocytes for optimal function, which may be related to myeloperoxidase and ribonucleotidyl reductase deficiencies.

In summary, nutritional deficiency can cause increased colonization of the intestine with microorganisms, alter the symbiotic characteristics of resident intestinal bacterial populations, and impair defenses of the gastrointestinal tract, allowing increased risk of systemic spread of infection and absorption of macromolecules (in particular, endotoxin).

13.3.4.4 INTESTINAL MICROFLORA

Indigenous microflora greatly impede colonization of the gastrointestinal mucosa by pathogenic organisms. The ability of a potential pathogen to initiate an infection depends on its ability to breach the mucosal epithelial barrier. One mechanism by which the normal flora inhibit establishment of pathogens is by preventing adherence of the pathogen to mucosal cells by occupying the site or by stearic hindrance.[102–105] Resident microbes also produce byproducts such as antibacterial factors that allow symbiosis rather than competition between them. Another hindrance mechanism is production of volatile fatty acids by normal microbial digestive processes to create an environment that is toxic to many bacterial populations, particularly the Enterobacteriaceae.[106]

13.3.5 Factors Affecting Motility

Disturbances in motility patterns occur during inflammatory diseases of the colon, but the role of motility alterations in the pathogenesis of diarrhea remains unclear. Invasive bacteria cause characteristic motor patterns in the colon consisting of rapid bursts of motor activity that appear to decrease transit time through the large intestine. The result is reduced clearance of bacteria from the large intestine, which may contribute to the virulence of the organism.[107] Absorption of endotoxin and the release of inflammatory mediators such as prostaglandins disrupts the motility patterns of the large intestine, resulting in less coordinated contractions, and may contribute to the alterations in motility seen with invasive bacteria. Although the effect of endotoxin and prostaglandins on transit time is not profound, the disruption of coordinated activity may play a role in causing diarrhea.[108] Thorough mixing and prolonged retention time of ingesta are important not only in microbial digestion of nutrients but also in absorption of microbial byproducts and fluid.[32,109] The ingesta is viscous and therefore must be mixed to bring luminal ingesta in contact with the mucosa for absorption.[109] In addition, poor mixing increases the thickness of the unstirred layer, decreasing contact of ingesta with the mucosa and decreasing absorption.[32,109]

Progressive motility must be present, however, if a diarrheal state is to occur.[32,109] Ileus may be accompanied by 793
increased fluid in the lumen of the large intestine, but without progressive motility the fluid is not passed. 794
Frequently, acute colitis causes a period of ileus characterized by scant stool. Diarrhea is apparent only when motility returns and the ingesta is passed. Increased progressive motility has been suggested to cause diarrhea by decreasing transit time and is thought to play a role in irritant catharsis and in the mechanism of action of some laxatives.[110] Irritation and distention increase motility and may well decrease transit time, but increased secretion also is thought to contribute to diarrhea caused by these substances.[111]
